Between 1st December 2020 and 31st March 2022, we conducted a cross-sectional study in the Cardiovascular Rehabilitation Clinic from Iasi Clinical Rehabilitation Hospital, on a group of patients with HF. For their classification, we used the Dutch Lipid Clinic Network (DLCN) score as it follows: if the score was above 8, they were classified as a certain FH case, probable case if the score was between 6-8, possible between 3 and 5 points, and unlikely to suffer from FH under 3 points. We decided to adjust the DLCN score using a correction factor validated in previous studies (6), because a great part of the patients had in their chronical prescription LLT. Consequently, if the patient has not been treated for high LDL for more than 6 months, was considered to be without conical treatment. For those who followed one LLT, the value was adjusted so that the impact of the treatment could be observed An important note is that the correction factor differs depending on the type of statin and dose, alone or in association with ezetimibe.

Study Participants

From a total number of 2005 patients admitted in the specified period of time, 32 patients were accepted in our research. The inclusion criteria were the age between 18-54 and more than 8 points in the Dutch Lipid Clinic Network score. We excluded patients diagnosed with severe hepatic or renal impairment, unbalanced diabetes, nephrotic syndrome, hypothyroidism, or those who ate a great amount of saturated and trans-unsaturated fatty acids.

Patients Evaluation

In order to avoid subjectiveness one investigator performed both the anamnesis and the clinical examination. Demographic data included: age, gender, BMI, degree of education (gymnasium, high school, university, and 10 classes or less), and employment status (working full time, part-time, retired or not working).

Some of the measurements performed from the blood samples were : Hb (mg/dL), uric acid (UA, mg/dL), proteins (g/dL), TC (mg/dL), triglycerides (mg/dL), HDL (mg/dL), LDL (mg/dL). These laboratory tests performed using the Erba XL 1000 Spectrophotometer® (Erba Diagnostics,

Mannheim, Germany).

Besides clinical and biological data, we applied a food frequency questionnaire that included information about eating habits, triggers for overeating, and feelings felt afterwards.

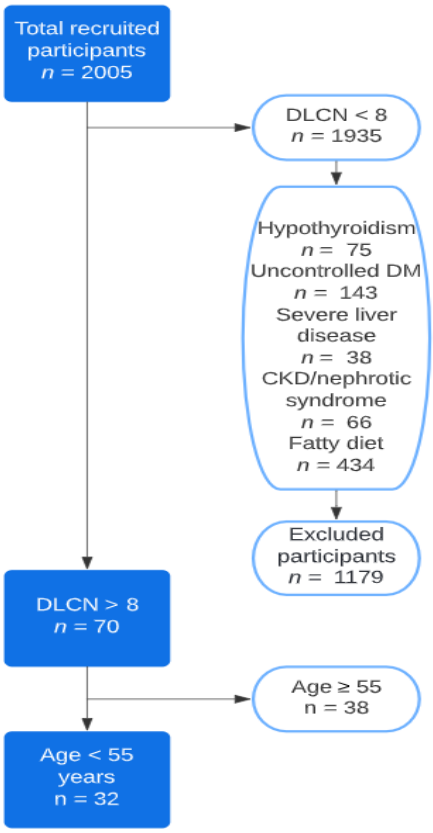

Fig. 1. Flow chart of the studied population

Ethical Approval

In order to be enrolled in the research, all of the patients had to complete a written informed consent form. Our study had received the approval from the Ethics Committee of both "Grigore T. Popa" University of Medicine and Pharmacy Iasi (certificate of approval dated 15th June 2020) and Iasi Clinical Rehabilitation Hospital (certificate of approval 25th November 2020).

Statistical Methods

Statistical analysis was performed using *SPSS 20.0* (Statistical Package for the Social Sciences, Chicago, Illinois). Data were expressed as mean ± standard deviation for continuous variables with normal distribution, as median with interquartile range for variables in which the normality of the distribution is not observed, and as the number of cases with frequency expressed as a percentage, in the case of categorical variables. In the case of continuous variables with normal distribution, the comparisons were made by applying the T-test for independent samples, or the ANOVA test,

for the comparison of more than two independent subgroups. The comparison of continuous variables that do not respect the normal distribution was performed using nonparametric tests: the Mann-Whitney's test, for the comparison of two subgroups, respectively the Kruskal-Wallis test, for the comparison of more than two subgroups. The comparison of the categorical variables was done using the Chi-square test. The correlation between different variables was evaluated by applying the Spearman correlation test. Statistical significance for all statistical tests performed was defined by a p-value <0.05.

RESULTS

Our study group included 32 patients, of whom 19 were women and 13 men. The average age was, respectively. We noticed that most of them came from urban areas (78.9% *versus* 84.6%), had higher education (63.2% *versus* 53.8%), and were employed full-time (84.2% *versus* 84.6%).

The evaluation of the body mass index revealed a higher average in the case of men, the difference being statistically significant (p=0.015).

TABLE I

Characteristics of the study group

	Female	Male	p-value
Age	43.78±9.41	44.15±9.04	0.869
Place of origin			
Rural	4 (21.1%)	2 (15.4%)	0.687
Urban	15 (78.9%)	11 (84.6%)	
Last form of graduated education			
Gymnasium	1 (5.3%)	1 (7.7%)	
10 classes/less	2 (10.5%)	1 (7.7%)	0.909
Highschool	4 (21.1%)	4 (30.8%)	
University	12 (63.2%)	7 (53.8%)	
Employment status			
Full time working	16 (84.2%)	11 (84.6%)	0.933
Retired	1 (5.3%)	1 (7.7%)	
Not working	2 (10.5%)	1 (7.7%)	
BMI	25.49±4.74	29.60±3.85	**0.015**
Blood samples			
Hemoglobin	12.41±1.08	14.88±0.79	**0.000**
Uric acid	3.07±1.14	4.67±0.85	**0.000**
Proteins	7.18±0.39	7.19±0.28	0.904
TC	260.21±56.93	283.20±78.66	0.344
TG	110.75±53.83	247.05±120.30	**0.002**
HDL	62.51±14.55	50.93±17.32	**0.050**
Non-HDL	197.69±54.36	232.26±78.24	0.150
LDL	177.84±48.41	203.10±66.89	0.224
LDLc	286.66±70.04	311.17±107.30	0.439

HDL – high-density lipoprotein; LDL – low-density lipoprotein; LDLc – corrected low-density lipoprotein; TC – total cholesterol; TG – triglycerides.

Regarding the laboratory tests, we notice significant differences in the value of hemoglobin, uric acid, and HDLc, but what stands out most is the difference between the average values of triglycerides, in men being much higher (247.05 ± 120.30 *versus* 110.75 ± 53.83, p = 0.002).

The diagnosis of familial hypercholesterolemia was made using the Dutch Lipid Clinic Network Score, criteria widely used in the European countries. Table II describes each criterion from the DLCN score and their frequency in the patients included in our study.

TABLE II

Dutch Lipid Clinic Network diagnostic criteria applied to the studied population

DLCN Criteria	FH
First-degree relative	
Premature CVD	16 (50%)
LDL > 95th percentile	11 (34.4%)
Tendinous xanthoma a/o arcus cornealis	7 (21.9%)
Child with LDL-C > 95th percentile for age and sex	14 (43.8%)
Personal history	
Premature CVA/PVD	4 (12.5%)
Coronary artery disease	10 (31.3%)
Physical examination	
Arcus cornealis < 45 years of age	18 (56.3%)
LDL	
155–189 mg/dL	0 (0%)
190–249 mg/dL	12 (37.5%)
250–329 mg/dL	10 (31.3%)
> 330 mg/dL	10 (31.3%)

FH: familial hypercholesterolemia; CVD: cardiovascular disease; LDL: low-density lipoprotein; CVA: cerebrovascular accident; PVD = peripheral vascular disease.

In table III the food questionnaire results are presented regarding how often certain specific food groups or foods are consumed.

Two-thirds of patients eat bread daily, regardless of gender. We notice that women tend to consume pasta more frequently, 94.7% prefer them a maximum of 3 times a week, unlike men. In their case, the percentage decreases by 10%.

Potatoes remain a staple food, being chosen on the menu almost daily, probably offset by the presence of other vegetables. We notice a food deficit when it comes to fruit, especially for men: only 23.1% have a portion of fruit every day, the percentage doubling for women (42.1%). Dairy products are also consumed with a low frequency, with less than a quarter of the participant consuming them daily.

When we evaluated the consumption of meat, we noticed that chicken is consumed 2-3 times a week by 76.9% of men and only 42.1% of women, who prefer pork/

beef. The vast majority of patients consume fish in less than 2 meals/week.

Fried food is chosen less than 3 times a week by 73.6% of women. But men eat more often, appearing even 4-6 times/week in the case of 46.2% of the subjects.

Soft juices and fast food have a low frequency in the weekly menu, regardless of gender.

TABLE III

Eating habits for female and male patients diagnosed with FH

	Female	*Male*
Bread		
<2x/week	1 (5.3%)	1 (7.7%)
2-3x/week	2 (10.5%)	2 (15.4%)

Daily	0 (0%)	1 (7.7%)
Fast-food		
<2x/week	13 (68.4%)	10 (76.9%)
2-3x/week	5 (26.3%)	2 (15.4%)
4-6x/week	1 (5.3%)	0 (0%)
Daily	0 (0%)	1 (7.7%)

DISCUSSION

Food choices can be explained primarily by characteristics of the studied group. It consists mainly of young people with secondary-higher education, from urban areas, employed full time.

The average BMI is above normal for both women and men. However, we note that male subjects are closer grade 1 obesity, while women have a slightly higher value than normal. Similar results were also published by Liberopoulos *et al* . that observed a higher BMI in male patients with FH compared to women. Moreover, the researchers declared that men usually are diagnosed earlier with FH than women, due to their unhealthier lifestyle (7). When it comes to laboratory tests, we see high levels of uric acid and triglycerides in men, possibly explained by overeating, and sitting in front of a screen for long times, these being also evidence for the increased values of BMI discussed above. Regarding the triglycerides values, similar results were published recently by Borg *et al.* who evaluated the lipid profile in patients with FH from Faroe Islands. The authors observed higher median triglycerides values in men than women, values that were increased even since childhood and had a maximum around 45-50 years. On the other hand, women had almost constant values in all the age groups (8). Another study conducted by Iyen *et al* . that included 3553 patients with FH from 1st January 1980 to 20 December 2010, observed that women had statistically significant lower values of the triglycerides compared to men. Also, the BMI in men was higher when compared to women (9).

One aspect that should be mentioned is the increased value of HDL cholesterol in women, with an average of 62.51 ± 14.55, as opposed to men, who have 50.93 ± 17.32, a sign that women's food choices are more thoughtful. Moreover, we have included in our study young and middle-aged women. Thus, most of them are premenopausal and do not have a proatherogenic lipidic profile, having therefore high values of HDL cholesterol. These findings are supported also by Wang *et al* . (10) and by Iyen *et al* (9).

Given that the articles evaluating the nutrition of patients with HF are extremely few, we have initiated a series of studies on this topic. The first choice to evaluate nutrition was the frequency food questionnaire, a validated, easy-to-apply tool that gave us valuable, starting information about the eating habits of this category of patients.

The main observations are that there is a discrepancy between the diet of men and women. Men tend to eat more potatoes, chicken, fast-food, and fried food, and the last two categories appear even daily in the menu of a small percentage of men. A pertinent explanation is the daily work schedule that limits the culinary choices of men, who prefer to eat outside during breaks, so they choose accessible dishes. The same results were obtained also by Grzymisławska *et al.* that published in 2020 an article that mentioned the fact that men eat more fried and fatty meals or sweets in front of the television (11). Masella and Malorni agree also with the results mentioned above, observing the opposite types of meals between men and women: while men have a high fatty meal, women tend to eat more vegetables and whole food (12). No female consume fried food or fast food daily.

Even if women eat pasta more often the triglycerides value is significantly lower. A

possible explanation might be the larger portions for men, who probably have other sources of carbohydrates.

Women eat more fruits and vegetables but even so, the daily intake is reduced for both genders. Similar results were published by a group of researchers that evaluated more than 3,500 subjects from Lebanon where females have a higher intake of fibers and fruits compared to males (13).

About dairy products, about 25% of men and women eat them 4-6 times per week, while approximately 20% of women and only 15% of men eat them daily. Heuer *et al.* evaluated the eating habits of Germans and Regarding the dairy products, the males aged up to 50 years old ate more cheese, dairy products, and milk compared to women, while the ratio was inversely proportional when considering the age group 35-80 years old (14).

CONCLUSIONS

Further research is necessary in order to apply even more accurate nutritional assessments, thus including in the research team in addition to the cardiologist, internist, and psychologist, the nutritionist. Correct patient information is as important as the medical treatment, ensuring better compliance with lifestyle changes. Prevention should be initiated from the family doctor's office, adherence to treatment increasing with the confidence in the medical staff. The training of specialists in lipidology is imperative for a comprehensive assessment of the patient with FH.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding the scientific research.

NEWS

CLINICAL FEATURES AND MANAGEMENT OF HUMAN MONKEYPOX: A RETROSPECTIVE OBSERVATIONAL STUDY IN THE UK

Human monkeypox is a zoonosis caused by monkeypox virus, an orthopoxvirus and close relative of variola virus (smallpox). It was first reported in central Africa in 1970 and has historically affected some of the poorest and most marginalized communities in the world. The clinical syndrome is characterized by fever, rash, and lymphadenopathy. Complications of monkeypox can include pneumonitis, encephalitis, sight-threatening keratitis, and secondary bacterial infections. Case fatality rates ranging from 1% to 10% have been reported in outbreaks in the Congo Basin and the virus clade circulating in this region appears to be associated with higher virulence. Human-to-human transmission of monkeypox is well described, including nosocomial and household transmission. However, human-to-human chains of transmission have historically been less well recognized. Two oral drugs, brincidofovir and tecovirimat, have been approved for treatment of smallpox and have demonstrated efficacy against monkeypox in animals. Our aim was to describe the longitudinal clinical course of monkeypox in a high-income setting, coupled with viral dynamics, and any adverse events related to novel antiviral therapies. We reviewed all cases since the inception of the HCID (airborne) network between Aug 15, 2018, and Sept 10, 2021, identifying seven patients. Of the seven patients, four were men and three were women. Three patients were treated with brincidofovir (200 mg once a week orally), all of whom developed elevated liver enzymes resulting in cessation of therapy. One patient was treated with tecovirimat (600 mg twice daily for 2 weeks orally), experienced no adverse effects, and had a shorter duration of viral shedding and illness (10 days hospitalization) compared with the other six patients. One patient experienced a mild relapse 6 weeks after hospital discharge. Human monkeypox poses unique challenges, even to well-resourced health-care systems with HCID networks. Prolonged upper respiratory tract viral DNA shedding after skin lesion resolution challenged current infection prevention and control guidance. There is an urgent need for prospective studies of antivirals for this disease (Adler H, Gould S, Hine P, *et al.* Clinical features and management of human monkeypox: a retrospective observational study in the UK; *Lancet Infect Dis* 2022 Published Online May 24, 2022 / https://doi.org/10.1016/ S1473-3099(22)00228-6).

CLINICAL PROFILE ASSOCIATED WITH BLEEDING SMALL BOWEL TUMORS IN PATIENTS UNDERGOING CAPSULE ENDOSCOPY (Abstract): Since the development and implementation into clinical practice of the small bowel (SB) capsule endoscopy (CE), obscure gastrointestinal bleeding (OGIB) is no longer an answerless question. In many cases of SB pathology, a definite diagnosis is made by SBCE, while other cases, as SB tumors (SBT), require additional investigations. Our aim was to identify predictors for SBT as OGIB etiology. **Material and methods:** We retrospectively studied all patients with OGIB who underwent SBCE in a two-year period. Only patients with positive findings were included. Patients with SBTs were compared to patients with non-tumoral cause of OGIB, and analyses for possible associated clinical factors were performed. **Results:** 205 SBCE examinations were performed for OGIB. Positive findings were noted in 134 patients (male gender: 72, female gender: 62; age range 21-79): 25 cases of SBTs, and 109 cases with non-tumoral causes responsible for bleeding (angioectasia, Crohn's disease, NSAIDs enteritis, and other). SBT patients underwent further investigations, for confirmation and stadialization. Patient's age < 65 years, lack of anticoagulant treatment, and overt type of bleeding significantly associated with SBTs. Gender was not predictor for SBT. Surgery was the main therapeutic option for SBTs, significantly more frequently compared to the non-tumoral causes. **Conclusion:** Young age, overt bleeding and lack of anticoagulant treatment are factors associated with the final diagnosis of SBT. Because SBCE is only a visual technique and additional investigations are needed, predictors could anticipate the need for additional explorations and could help optimizing the investigational plan in terms of time and resources. **Keywords:** SMALL BOWEL TUMOR, OBSCURE GASTROINTESTINAL BLEEDING, IRON DEFICIENCY ANEMIA, SMALL BOWEL CAPSULE ENDOSCOPY.

Small bowel capsule endoscopy (SBCE) has revolutionized the approach of patients with suspected small bowel (SB) pathology. Since its launch and its implementation into the clinical practice more than two decades ago, SBCE has become an essential tool in the exploration of the gastrointestinal tract, allowing the diagnosis and warranting the choice of the appropriate management in many types of SB patholo-

gy (1). Actual guidelines from all over the world are now consensually sustaining the use of SBCE as first-line investigation whenever SB pathology is suspected unless absolute contraindication exists (2-4).

SBCE has made important contributions in the diagnostic work-up of obscure gastrointestinal bleeding, unexplained iron deficiency anemia (IDA), inflammatory bowel diseases - especially Crohn's disease and inflammatory disease type unclassified, celiac disease, and small bowel tumors (SBT).

Since the use of SBCE, and thanks to various technical progresses aiming to improve its performance, OGIB is no longer an answerless question. Suspected small bowel bleeding, recognized recently as separate entity called middle gastrointestinal bleeding, represents the main indication for SBCE (5). Diagnostic yield of SBCE in suspected SB bleeding has raised to almost 70%, and the most frequent lesions found to be responsible are angiodysplasia, Crohn's disease, various types of enteritis, and SBT (6, 7).

Traditionally, SBT are considered relatively rare, counting 5-8% from all gastrointestinal tract tumors (8). Small bowel is classically considered the most challenging part to be explored form the whole gastrointestinal tract, due to its "hidden" location, length and lack of ideal approach methods, both effective and safe. Not so long ago, data were showing that SBCE has doubled the rate of SBT diagnosis (9). According to recent analysis, SBCE has practically almost tripled it, the reason for this accomplishment being undoubtedly its capability to visualize in a relatively simple, non-invasive manner the entire small bowel (10). On the other hand, the most frequent circumstance for detecting SBT by SBCE is obscure (manifest or occult) gastrointestinal bleeding.

However, SBCE offers only a macroscopic view of the lesion. Therefore, the final and complete diagnosis of SBT is established after further investigations allowing histopathological analysis and, respectively, stadialization, or even only after surgical approach. Even if SBCE is the first line investigation for suspected SB pathology, any suspicion of SBT will require supplementary investigations. Thus, in terms of resources, anticipating the need of more explorations could optimize the work-up strategy.

Our aim was to identify predictors for SBT as cause of OGIB, so in the high probability of SBT, additional work-up should be timely previewed and consequently provided.

MATERIAL AND METHODS

Study design and patients

We retrospectively analyzed the clinical data and medical records of all patients with OGIB (overt or occult) who underwent SBCE in a two and a half-year period, from January 2019 to June 2021 in our tertiary referral care center. Only patients with positive findings, which were further concordant with the final diagnosis, were included in the final analysis.

This study was performed in accordance with the ethical principles of the Declaration of Helsinki and was approved by the institutional review board. All patients underwent SBCE examination after informed consent was signed. No additional consent was required for this study owing to its retrospective nature.

SBCE procedure

The third-generation CE system (PillCam SB3) was used, in combination with

RAPID reading software. All the procedure were performed after negative upper and lower gastrointestinal endoscopy. Patients were informed about the procedure and signed the informed consent. SBCE examination was performed after contraindications were excluded. They were prepared according to current guidelines, with 2 liters of polyethylene-glycol electrolyte lavage solution the day before the examination. Saurin's classification was used for potential small bowel bleeding lesions (11).

Data collection

Patient-related variables, including age, gender, type of OGIB, and current anticoagulant treatment, were reviewed. The patients were classified into two groups according to the final diagnosis: patients with SBT and patients with non-tumoral cause for OGIB, respectively. The two groups were compared in order to assess clinical parameters associated with the diagnosis of SBT.

Statistical analysis

Categorical variables were reported as frequencies and percentages. Continuous variables are presented as mean ± standard deviation values, and differences between groups were statistically assessed using Fisher's exact test. A two-sided P value of < 0.05 was considered statistically significant Statistical analyses were performed using *SPSS version 22.0* software (IBM SPSS Inc, Chicago, IL, USA).

RESULTS

Baseline characteristics of patients and diagnostic yield of SBCE in OGIB

In total, 205 patients underwent SBCE for OGIB in the above-mentioned period. SBCE found the responsible lesion in 134 patients, corresponding to a diagnostic yield of 65%.

The clinical characteristics of the 134 patients entering our study are presented in the Table I. We have noted a slight predominance for male gender among all patients. The majority of patients belonged to the young age group (age < 65 years), and the most frequent type of bleeding was the occult one. Approximatively one fifth of the examined patients were taking anticoagulants, for associated cardio-vascular or neurological diseases.

TABLE I.

Clinical characteristics of patients, findings at SBCE and type of intervention

	Total number of patients = 134

Medical treatment	82
Endoscopic treatment	27
Surgery	25

Findings at SBCE

The interpretation of the lesions discovered by SBCE was made according to Saurin's classification. Following SBCE, SBTs as etiology for OGIB were noted for 25 patients (18.6%), while for the remaining 109 patients (81.4%), non-tumoral causes were recorded. After complete work-up, consisting in further imaging or enteroscopic investigations and/or surgical approach, a final histological diagnosis was established. The most frequent types of tumors were GIST and adenocarcinoma. Cases of neuroendocrine tumor and lymphoma were also recorded, as well as a case of jejunal ulcerated lipoma. Amid non-tumoral causes, the most frequent were represented by angioectasia, Crohn's disease, NSAIDs enteropathy, and enteritis; other lesions were also described (diverticulum, parasitosis, intestinal tuberculosis).

The final management of the cases, consisted in medical treatment for the majority of cases, endoscopic or surgical treatment, according to the positive diagnosis. SBCE procedure-related complications, such as retention, did not occur in any of the cases.

Correlations between clinical characteristics of patients and the etiology of OGIB

The results of the analysis regarding patients' age, type of bleeding, concomitant anticoagulant treatment according to the etiology of bleeding (tumoral lesion vs. non-tumoral cause, respectively) are showed in the Table II. Age group under 65, overt type of OGIB and lack of anticoagulant treatment significantly associated with SBT as cause of OGIB ($p<0.05$).

The comparative analysis regarding the need for further investigations and the type of therapeutic intervention according to the same two groups is shown in the Table III. With one exception, all the rest of the patients with SBT (24 out of 25) required additional investigations, significantly more compared to the patients with non-tumoral cause of OGIB (25 out of 109, respectively; $p<0.001$). In the same time, significantly more patients with tumoral bleeding needed surgery as therapeutic solution, while the most patients with non-tumoral bleeding were treated by medical or endoscopic interventions ($p<0.0001$).

TABLE II.

Clinical characteristics according to the etiologic diagnosis

DISCUSSION

SBT are rare, and their diagnosis is difficult. Clinical presentation of SBT is often non-specific. Even when the clinical index suspicion is high, choosing and applying the right methods of exploration is difficult. These are main the reasons for why, generally, the approach of the small bowel is considered a challenge.

After having proved along the years the usefulness, together with its non-invasive character, SBCE became the first line investigation method recommended when small bowel pathology is suspected.

However, a positive diagnosis at SBCE examination is not always the final diagnosis. The identification and the right description of a typical, benign lesion at SBCE usually represents the last step before applying the right treatment, but the diagnosis of SBT in patients undergoing SBCE is usually an intermediate cornerstone across a long investigational path. Finding a tumoral mass at SBCE is followed, as appropriate, by anterograde or retrograde enteroscopy with biopsy, and further entero-CT or entero-IRM in order to establishing the extension.

At the same time, another challenge in the diagnosis of SBT are represented by the cases of false SBT, which require, especially in the case of submucosal lesions, thorough differential diagnosis with the bulges having similar appearance. Several criteria and scores have been proposed along the years, as predictive methods to differentiate between the true masses and the innocent bulges (12, 13).

Thus, knowing the factors associated with the SBT could help anticipate the diagnosis and plan in a timely manner the diagnostic sequence and the therapeutic decision.

Epidemiological studies showed that, according to gender, men are more prone to develop malignant SBT (14). In our analysis, there was a higher predominance of male patients in the SBT group, but male gender was not predictive for the diagnosis of SBT.

In our study, the main indication for OGIB was represented by the occult bleed-

ing, with IDA. A significant lower proportion of patients with occult OGIB had tumoral lesions as cause for their anemia (8%), while more than one third of patients with overt OGIB had SBT at SBCE (36%, $p<0.05$). Consequently, overt OGIB associates with higher frequency of SBT diagnosis. Lower diagnostic yield of SBCE in IDA, compared to overt bleeding, has been stated by many studies so far (15,16). Additionally, anemia itself has many and often combined causes and mechanisms and may become relatively common in the elderly population. Thus, when SBCE is performed for IDA, there are usually less chances to have a diagnosis. This is also how we could further explain the higher proportion of patients aged under 65 in the SBT group, compared to that in the non-tumoral group (84% *versus* 61%, respectively, $p = 0.27$).

Anticoagulant treatment was associated in our analysis with the non-tumoral cause of OGIB. Minor lesions bleeding may be triggered by the anticoagulant medication. In the lack of anticoagulant drugs, they would have probably remained silent. So, minor lesions are prone to manifest and be discovered more frequently when the patient follows this type of treatment, for various, especially cardio-vascular, comorbidities. SBT present a bleeding potential by themselves, so they do not need an extra trigger factor for hemorrhagic exteriorization.

As discussed before, identifying a tumoral mass at SBCE implies further work-up. In our study, in order to complete the diagnosis, all patients with SBTs underwent additional investigations (enteroscopy with biopsy, entero-CT, and/or entero-IRM), while only 38% of patients with non-tumoral lesions at SBCE needed supplementary exploration before the therapeutic decision ($p<0.05$).

Depending on the type, dimension and extension, SBTs have usually surgical indication. In our study, one single SBT was benign, with the final histological diagnosis established after surgery - jejunal ulcerated lipoma. The bleeding potential, and the lack of a histological diagnosis after enteroscopy with biopsy, justified the surgical approach. Metastatic SBTs are rare, but they exist, and they may complicate with bleeding; a particular case of metastatic melanoma was diagnosed in our analysis with metastatic melanoma, managed by conservative treatment, with no surgery involved. The other case in our study which did not require surgery was a case of SB lymphoma, which was referred to the hemato-oncologist.

Capsule retention is a complication with 1-2% overall occurrence rate, with various frequencies reported depending on the indication of the examination, the highest in known CD (17, 18).

For OGIB, retention rate was 1.3% in a large European single-center 10-year experience (19). Nor retention or other complication occurred in our analysis, probably due to the prior work-up which excluded patients with high obstruction risk from the SBCE examination.

CONCLUSIONS

Age under 65, overt bleeding and lack of anticoagulant treatment sketch the profile of the patients with SBT; these patients will also be those who will require additional investigation methods and, finally, will have surgery as therapeutic option.

A complete early characterization of the clinical profile of the patient is of upmost importance, before deciding the diagnostic work-up. Some clinical characteristics may associate, as we showed, with a higher probability of having a tumoral lesion responsi-

ble for their bleeding. Being prepared of advance in front of such patients may assure a temporal gain and a more fluent investigation algorithm, finally reflected into the right therapeutic option choice.

BEYOND RESPIRATORY DAMAGE-NEUROLOGICAL INVOLVEMENT IN SARS-Cov-2 INFECTION (Abstract): Although the respiratory damage associated with SARS-CoV-2 infection is well known, clinical and experimental studies have shown that the *Coronaviridae* family has a certain tropism for both the central and peripheral nervous system. Most patients with this pathology also associate neurological manifestations, often of a central type, with varying degrees of difficulty. The aim of this study was to evaluate the newly developed neurological manifestations in SARS-CoV-2 infected hospitalized patients. Material and method: We retrospectively analyzed medical records of patients with SARS-CoV-2 infection admitted in the Clinical Hospital of Infectious Diseases "Sf. Parascheva" Iasi between May 2020 – May 2022. Clinical features, frequency and correlation with risk factors (for example age, gender, comorbidities) and also severity of infection were evaluated. **Results:** We have identified 133 patients hospitalized during analyzed period and the majority presented significant comorbidities (94.84% cases). Fatigability (51.88% cases), myalgia (32.33% cases), impaired consciousness (decreased consciousness or confusion to encephalopathy) (27.88% cases), headache (28.57% cases) were the most frequent neurological features identified. A changing pattern in neurological manifestations was found during the pandemics' waves, with an increase of incidence of fatigability and myalgia during the fifth wave of pandemic. **Conclusions:** Neurological symptoms were a relatively constant part of the clinical picture of SARS-CoV-2 infection. They had polymorphic and various features during the pandemic waves. The incidence of headache, myalgia and fatigability was highly increased during the last wave of pandemics. Impairment of consciousness was significantly correlated with age, neurological and cardiovascular comorbidities. **Keywords**: SARS-CoV-2 INFECTION, NEUROLOGICAL, HEADACHE, CONFUSION.

Declared in March 2020, the COVID-19 pandemic was associated with over 650 million illnesses or relapses and over 6 million deaths (1). The pathophysiology of the illness, a description of the clinical manifestations, the discovery of an efficient and secure etiological treatment, and last but not least, the identification of suitable particular prophylaxis measures were all necessary for the face of an emergent infection. These factors required special consideration and quick understanding. Under the pressure of the unceasing evolution of viral transmission in parallel with the high number of illnesses,

the therapeutic approach was constantly followed and updated national and international protocols, aiming at the most effective treatment depending on the severity and risk factors of the infection. The SARS-CoV-2 infection affected people of all ages, and the risk factors for the severe infection, such as newborns, prematurity, elderly, or male gender, were found (2). Pre-existing pathologies such as obesity, diabetes, cardiovascular and renal diseases, chronic respiratory diseases, or immunosuppression were risk factors for all age groups throughout the pandemic (2,3).

Clinical manifestations of SARS-CoV-2 infection include:

- fever, chills, rigor.
- respiratory: cough, odynophagia, dyspnea, thoracic pain.
- digestive: nausea, vomiting, diarrhea.
- cutaneous: maculopapular/morbilliform, urticarial, and vesicular eruptions and transient livedo reticularis.
- neurological: headache, myalgia, anosmia, ageusia or dysgeusia, fatigability, confusion, dizziness. Rare cases of myositis, rhabdomyolysis, paresthesia, Guillain Barre syndrome and focal and multifocal neuropathies (e.g., facial nerve palsy, lower cranial neuropathy (vagus, accessory, and hypoglossal; Tapia syndrome or multiple cranial neuropathies) were also reported (4-6).

The SARS-CoV-2 virus produces neurological manifestations through various mechanisms, either by direct action secondary to the invasion of the CNS through the blood–brain barrier, via the hematogenous route attached to the ACE2 receptors or by infecting the nerve terminals of the vagus nerve located in the respiratory system and the gastrointestinal tract (7). The pathological changes secondary to hypoxemia, including acute hypoxic-ischemic damage and the proinflammatory state associated with the "*cytokine storm*" hypercoagulation, endotheliopathy, platelet activation, or cardio-embolism, are responsible for the neurological complications of SARS-CoV-2 infection (8). These complications are represented by encephalopathy, meningitis, encephalitis, acute necrotizing encephalopathy, or cerebrovascular disorders, such as stroke (6,8). The incidence of neurological manifestations and complications varied during the waves of the COVID-19 pandemic (9).

In this context, we performed a retrospective analysis of the clinical-biological, therapeutic and evolutive data of patients with SARS-CoV-2 infection who presented neurological manifestations and were admitted to the Clinical Hospital of Infectious Diseases "Sf. Parascheva" Iasi, between May 2020 and May 2022.

MATERIAL AND METHODS

This was a retrospective analysis of the hospital–based medical records of the patients with SARS-CoV-2 infection in patients with neurological manifestations hospitalized during the mentioned period. The study period was stratified based on the month of test screening and diagnosis to identify temporal trends in cases. Population data were divided into three phases:

- Phase I: May 2020–February 2021 (first three waves)
- Phase II: August–December 2021 (fourth wave)
- Phase III: January–May 2022 (fifth wave).

The clinical and paraclinical data were collected from observation files and reports. The following data were collected during the research: demographic data, medical and medicine history, the onset,

and severity of symptoms at admission (neurological, respiratory and other manifestations), treatment administered (name and duration of administration), and outcome (complications or death).

The severity of infection was graded as follows (5): *mild disease* - mild symptoms and normal or non-pneumonia findings on radiographic examination; *moderate disease* - respiratory symptoms and fever, with evidence of pneumonia on radiographic examination; *severe disease*: dyspnea, respiratory frequency ≥ 30/minute, blood oxygen saturation ≤ 93%, PaO_2/FiO_2 ratio < 300, and/or lung infiltrates > 50% of the lung field within 24–48 hours and c*ritically ill*: respiratory failure and mechanical ventilation required septic shock, and/or multiple organ dysfunction/failure and requires ICU monitoring and treatment.

Continuous data are expressed as means ± standard deviation. Pearson correlation coefficients were used for correlation between different variables. A p-value ≤ 0.05 was considered statistically significant. Statistical analysis was performed using XLSTAT software version 2022.

The Ethics Committee of the Infectious Diseases Clinic "Sf. Parascheva" Iaşi approved the study.

RESULTS

In the current analysis, we have included 133 patients corresponding to each phase, with a mean age of 65.5 years (range 25 – 92 years), mainly males (60%). In most of the cases were recorded metabolic (obesity or diabetes) and cardiovascular (e.g., hypertension), and only 5,26% of cases had no associated disorders (tab. I).

TABLE I.
Patients' characteristics

Statistic Variable	Comorbidities			Provenience Urban (U)/ Rural (R)	Gender Male(M)/ Female(F)	Statistic Variable	Age (years)	Weight (kg)	Height (m)
	Metabolic	Cardiov-ascular	Neurologic						
No. of observations	133	133	133	133	133	No. of observations	133	133	133
Rel. frequency per category (%)	42	52	9.77	71/29	59/41	Median	69	81.5	1.68
Lower bound on frequencies (95%)	32	41	0	64/21	50/33	Mean	65.49	86.36	1.7
Upper bound on frequencies(95%)	53	62	7	79/36	67/50	Standard deviation (n)	13.96	18.86	0.10
Proportion per category	0	1	0	1/0	1/0	Variation coefficient (n)	0.21	0.22	0.06
Lower bound on proportions (95%)	0	0	0	1/0	1/0	Lower bound on mean (95%)	63.08	78.91	1.66
Upper bound on proportions (95%)	1	1	0	1/0	1/0	Upper bound on mean (95%)	67.89	93.80	1.74

The most frequent neurological symptoms extracted from the medical records were experienced from the onset of infection to discharge, as follows: fatigability (51,88% cases), myalgia (32,33% cases), impaired consciousness (decreased consciousness or confusion to encephalopathy) (27,88% cases), headache (28,57% cases) and less frequent loss of smell (anosmia) or taste (ageusia) (fig. 1).

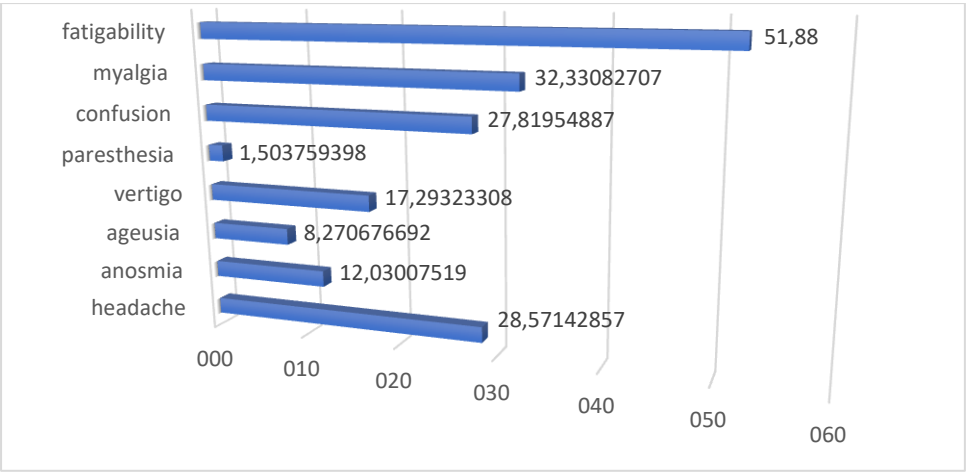

Fig. 1. Neurological manifestations

In our study, alterations in consciousness status prevailed during the fourth wave of pandemics (delta variant). At the same time, myalgia and fatigability were noted more often during the fifth wave, which was the omicron variant wave. Interestingly, the incidence of cases of headache decreased up to the last wave of pandemics (fig. 2).

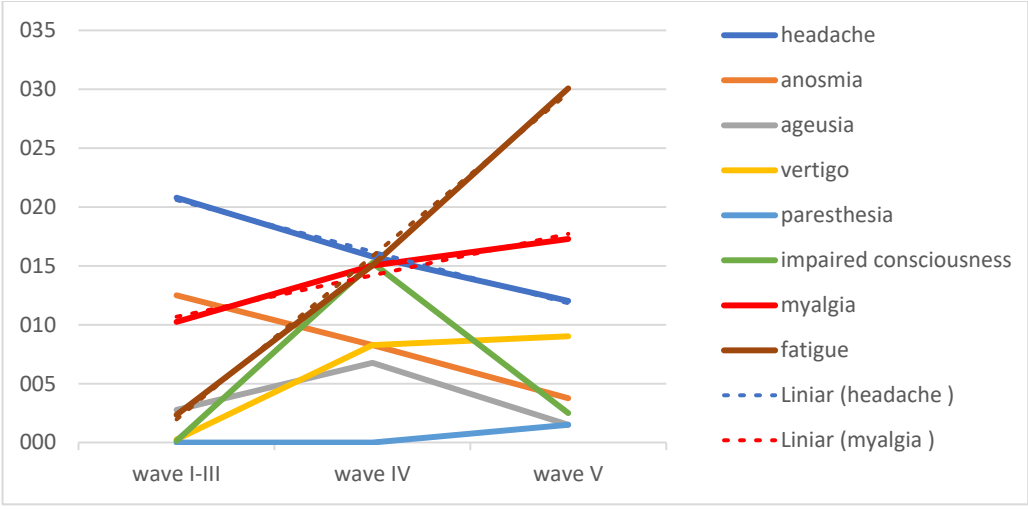

Fig. 2. Trends of neurological symptoms by pandemic wave (percentage of cases)

The Pearson correlation test did not find any link between neurological symptoms and risk factors like gender or comorbidities. Nevertheless, a weak but significant correlation was found between age, neurological and cardiovascular illnesses, and the different levels of altered consciousness (from confusion, disorientation, and somnolence to coma or encephalopathy) (tab. II).

TABLE II.

DISCUSSIONS

Declared in March 2020, the evolution in "waves" of the COVID-19 pandemic was the result of the very large number of mutations, especially at the level of the viral Spike protein. Emerging strains of the SARS-CoV-2 virus, with increased transmission capacity and high degree of infectivity, have been called "*variants of concern"* (VOC). The World Health Organization has established 5 VOCs of the SARS-CoV-2 virus, namely: Alpha (B.1.1.7), Beta (B.1.351), Gamma (P.1), Delta (B.1.617.2) and Omicron (B.1.1.529) with different characteristics (tab. III) (10).

The SARS-CoV-2 infection is mainly characterized by pneumonia, hypoxemic respiratory failure, cardiac and kidney dysfunction, and important morbidity and mortality. However, a varied range of manifestations with temporal trends depending on the wave and variant involved has been described in COVID-19 patients. Our findings are in line with previously published data (11-14). anosmia, ageusia/dysgeusia, headache, alterations of consciousness and myopathies were the most common neurological features identified in SARS-CoV-2-infected patients. Amin et al (2022) described the evolution of COVID-19 symptoms during the five waves based on the results from a population-based cross-sectional analysis. The incidence of neurological manifestations with peripheral involvement was increased during the third wave and prevailed during the last two waves. In our study, various levels of impairment of consciousness (from altered

mental status to encephalopathy) were identified mainly in the infection produced by the delta variant (9). These manifestations were expected mainly as a result of silent hypoxia described in patients with COVID-19 pneumonia (15). We have noted a very weak, but statistically significant correlation between these alterations and other negative prognosis factors in the evolution of SARS-CoV-2 infection, such as male gender, elderly, and other associated diseases (neuropsychiatric and cardiovascular diseases). The severity of these symptoms decreased towards the end of the pandemic, not only due to changes in the virulence of the virus but also due to the introduction of the anti-SARS-CoV-2 vaccination (16).

TABLE III.
Characteristics of main VOCs

WHO	Alpha	Delta	Omicron
Pango Lineage	B.1.1.7,Q	B.1.617.2, AY.4.2	B.1.1.529, BA
Transmission	↑ 43-82% transmissible	↑~↑↑ ≥alpha	↑↑↑ X3.19-4.2 more transmissible than delta
Severity	→/↑ X60% mortality	↑↑ X2 alpha Risk of hospitalization and death	↓ Severity and mortality low
Immunology	→	↑	↑↑
		high risk of reinfection	

The incidence of myopathies characterized by fatigability and myalgia significantly increased during the fifth wave, while other symptoms (e.g., loss of taste or smell) which were frequent at the beginning of the pandemic, were less often recorded in COVID-19 patients. The frequency of cases with headache was found decreased during the last two waves of pandemics, which is different from our clinical practice. This could be a result of the small sample size analyzed. Therefore, we will perform further analysis extending the number of patients.

The main limitation of our analysis is the small number of analyzed patients. The following studies will expand the study sample size and analyze in detail the correlations between the neurological manifestations, the severity of the disease and other known prognostic factors in SARS-CoV-2 infection.

CONCLUSIONS

Neurological symptoms were a relatively constant part of the clinical picture of SARS-CoV-2 infection. They had polymorphic and various features during the pandemic waves. The incidence of headache, myalgia and fatigability was highly increased during the last wave of pandemics. Impairment of consciousness was significantly correlated with age, but also with neurological and cardiovascular comorbidities.

IN VITRO ASSESSMENT OF TGFβ3/TGFβ1 RATIO VARIATION PATTERN FOLLOWING ANTISEPTIC TREATEMNT ON ADIPOSE-DERIVED STEM CELLS AND FIBROBLASTS IN 2D *VS*. 3D CULTURE SYSTEMS (Abstract): Wound management, especially chronic wounds and burns, remain a challenge despite advances regarding topical antimicrobial agents and emerging stem-cell based strategies. Moreover, the current available data is controversial regarding antiseptics drawbacks on wound healing and minimal on the effects on stem cells, although it seems they modulate cytokines, including TGFβ. The aim of the study was to evaluate *in vitro* the effects of commonly used antiseptics on the TGFβ3/TGFβ1 ratio in cell cultures. **Material and methods:** Four cell constructs were developed with different cell ratios using adipose-derived stem cells and normal human dermal fibroblasts in both 2D and 3D mono and co-cultures. Following treatment with either 1% povidone-iodine, 0.05% chlorhexidine digluconate or silver-coated dressing, TGFβ1 and TGBβ3 levels were evaluated using ELISA method. Subsequently, TGFβ3/TGFβ1 ratio was calculated, and statistical analysis performed. **Results:** TGFβ3/TGFβ1 ratio for untreated stem cells and co-cultures increase pattern follows the stem cell ratio in both 2D and 3D culture systems. Following povidone-iodine treatment for all cell constructs in 2D systems, TGFβ3/TGFβ1 ratio increases significantly, whereas in 3D culture systems increased only in stem cell monoculture and co-culture with fibroblast as a majority cell fraction. Moreover, there are significant differences in TGFβ3/TGFβ1 ratio when 2D and 3D culture systems are compared, especially after chlorhexidine digluconate and silver-coated dressing exposure for fibroblast monocultures and co-cultures. **Conclusions:** TGFβ3/TGFβ1 ratio pattern modulation *in vitro* is dependent on antiseptic, cell type, cell ratio and culture system. **Keywords:** TGFβ3/TGFβ1 RATIO, WOUND HEALING, ANTISEPTICS, SPHEROIDS, 3D CULTURES.

Wound care improved significantly, although management of chronic wounds, burns or any other wound at high risk of infection remains a clinical challenge (1,2). Often to either control the bacterial burden or to treat an infected wound, topical antimicrobial is used (3, 4). Also, emerging stem cell-based strategies represent an important topic in wound management (5).

Antiseptics are chosen based on antimicrobial spectrum and advantages and possible drawbacks on wound healing. One pa-

rameter used to choose an antiseptic is the biocompatibility index, which should be above 1, meaning a broad activity with minimal cytotoxicity on fibroblasts and keratinocytes (1, 4). Current available data on antiseptics effects on wound healing are heterogeneous and conflictual, difficult to translate *in vitro* data in clinical setups, with an insufficient standardized testing and evaluation methods and without any global guidelines available (1, 2, 4).

Most commonly used topical antimicrobial agents are povidone-iodine, chlorhexidine digluconate and silver based. The first two agents are used especially for wound irrigation, while silver based, such as silver containing dressing are recommended for infected wounds and not prophylactic (2, 4, 6). Povidone-iodine (PVI) is frequently used, although it is not recommended for chronic wounds due to its cytotoxicity and contraindicated in new-borns, pregnancy, thyroid disorder and for no more than 7 days (1, 4). Some data suggest that PVI promote wound healing by increasing TGFβ levels, even in the absence of infection (7). Chlorhexidine (CHX) is used for wound cleaning/irrigation, predominantly for burns. There is low evidence regarding wound healing impairment, including when compared with PVI. Moreover, it has a lower antimicrobial spectrum with no effect on Proteus spp., Pseudomonas aeruginosa and fungi (4, 6). Silver-coated dressings (Ag) seem to have anti-inflammatory effects, by modulating cytokine levels, including TGFβ. Also, some studies suggest that Ag, apart from a good antimicrobial effect, promotes wound healing (3, 4, 8).

TGFβ superfamily plays an important role throughout the wound healing process. TGFβ1 it is usually associated with dermal fibrosis, while TGFβ3 is known to decrease scar tissue formation. Also, when TGFβ3 to TGFβ1 ratio is increased, wounds tend to heal with less scarring (9, 10).

As the stem cell-based strategies emerge, there is limited data regarding antiseptic effects on adipose-derived stem cells (5, 11). Most *in vitro* studies are on fibroblasts and keratinocytes and using varying cell species. For example, murine fibroblasts tolerate better PVI compared with human fibroblasts, making more difficult to translate *in vitro* results in clinical settings (12).

Herein, as part of a larger study, we present the effects of the three most commonly used topical antimicrobial agents on human adipose derived stem cells (ADSC) and normal human dermal fibroblasts (NHDF) in different culture systems regarding TGFβ3/TGFβ1 ratio variation patterns.

MATERIAL AND METHODS

Antiseptics

Most commonly used antiseptics were selected: PVI (PVP1-100G, Sigma-Aldrich), CHX (C9394-25ML, Sigma-Aldrich) and a silver-coated dressing (66000808, Smith& Nephew). PVI and CHX were diluted in PBS and 1% PVI and 0.05% CHX selected as working concentrations. The 5/5 cm silver-coated dressing (Ag) was cut in 5/5 mm pieces that contain approximate 0.21-0.33 mg silver per mm^2.

Cells and cell constructs

Adipose-derived stem cells (PT-5006, Lonza) and fibroblasts (C12302, PromoCell), cultured at 37^0C, 5% CO_2, and in humidified atmosphere were used for both 2D and 3D models. For both cell culture systems, four cell constructs were developed: ADSC and NHDF monocultures; and

co-cultures with 80% ADSC and 20% NHDF (A80N20) and inverted ratio with 20% ADSC and 80% NHDF (A20N80). A 1:1 media mix was used for co-culture conditions (FGM-2 Bullet Kit, CC-3132, Lonza and ADSC™ Growth Medium, PT-4505, Lonza).

For 2D culture constructs, $5x10^3$ cells per well (final number) were seeded in either 96-well flat bottom plates (3904, Costar) or 24-well plates (CLS3527-100EA; Sigma-Aldrich) and incubated 24h. All conditions were treated for 30 seconds with PVI and CHX and 24h with Ag, followed by 2 washes with PBS. After treatment, fresh media was added and incubated for 3 days prior to ELISA sample collection.

Spheroids were generated using 96 ultra-low adherence plates (650979, Greiner), 1% Matrigel (356237, Corning), as previously described by Ivascu and Kubbies (13). For each cell condition $5x10^3$ cells/well were used, followed by 3 days incubation to allow spheroid formation. The spheroids were treated with antiseptics for 30 minutes with PVI and CHX and 72h with Ag, washed two times with PBS and incubated in fresh media for 5 days prior to sample collection.

Enzyme-linked immunosorbent assay (ELISA)

TGFβ isoforms levels were assessed using sandwich ELISA kits (TGFβ1 - ab100647, Abcam; TGFβ3 - LS-F2825, LSBio). Assays were performed according to supplier protocols, in duplicates. Plate reader SpectraMax i3 (Molecular Devices) was used to obtain absorbance values.

Statistical analysis

Data collection was performed using Excel. Absorbance values were used to generate standard curve interpolation in GraphPad to calculate cytokine levels. The results were used to calculate TGFβ3 to TGFβ1 ratio. Graphs and statistical analysis were performed with GraphPad software and one-way ANOVA with multiple comparation analysis (Sidak's multiple comparation test).

RESULTS

TGFβ3/TGFβ1 ratio pattern varies for untreated conditions, with cell type, cell ratio and culture system. When compared the untreated cell conditions in 2D culture systems, TGFβ3/TGFβ1 ratio increases as stem cells are introduced in the cultures conditions, with a statistically significant difference ($p < 0.015$, R^2 0.908) between fibroblasts and stem cell monocultures (fig. 1A). In 3D culture systems there are ratio shifts, but with no statistical significance. The ratio is increased for fibroblasts condition compared with stem cell monoculture (fig. 1B). Moreover, when stem cells are present, the ratio pattern is similar with 2D culture systems, increasing with the stem cell ratio (20% < 80% < 100% stem cells).

In 2D cultures after PVI treatment, TGFβ3/TGFβ1 ratio increases significantly for all cell conditions ($p < 0.0001$, R^2 0.9900) and the pattern variations follows the stem cell ratio. For stem cell monocultures, TGFβ3/TGFβ1 ratio increases significantly ($p < 0.0001$, R^2 0.9900) following treatment with all three antiseptics. For A80N20 the ratio increases also following CHX and Ag treatment, but with no significant difference for Ag; compared with A20N20 when following both CHX and Ag treatment, TGFβ3/TGFβ1 ratio shifts are minimal. The ratio increases also in fibroblast monoculture after exposure to CHX ($p < 0.0001$, R^2 0.9900). Moreover, when the response to the three antiseptics are

compared between cell culture conditions, the ratio increase is significant between PVI and both CHX and Ag ($p < 0.0001$, R^2 0.9900) (fig. 2A).

In 3D cultures, TGFβ3/TGFβ1 ratio variations following antiseptic treatment are less compared with 2D conditions. TGFβ3/TGFβ1 ratio increases significantly following PVI treatment only for stem cell cultures and A20N80 condition; and following Ag exposure for co-culture conditions ($p < 0.0087$, R^2 0.7668). Moreover, there was no significant differences between antiseptics (PVI ~ CHX ~ Ag) (fig. 2B).

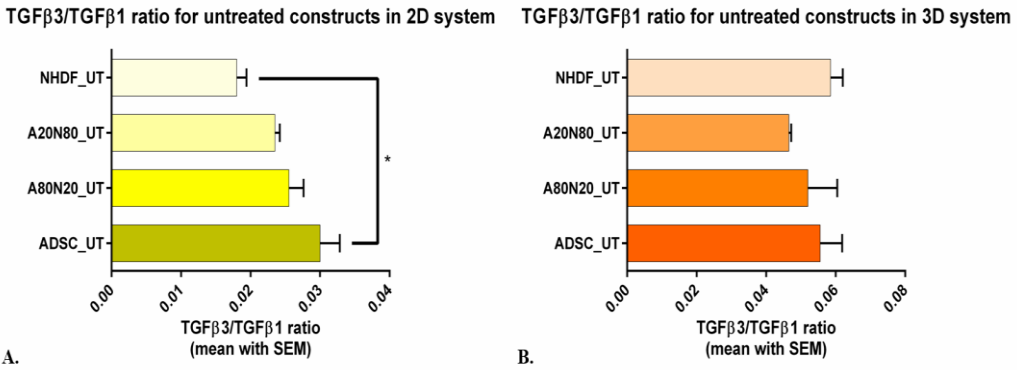

Fig. 1. TGFβ3/TGFβ1 ratio for untreated cell constructs: A. 2D system – Ratio increases significantly for ADSC monocultures compared with NHDF (*$p < 0.015$, R^2 0.908; CI 95%); B. 3D system – TGFβ3/TGFβ1 increasing pattern proportional with stem cell ratio.

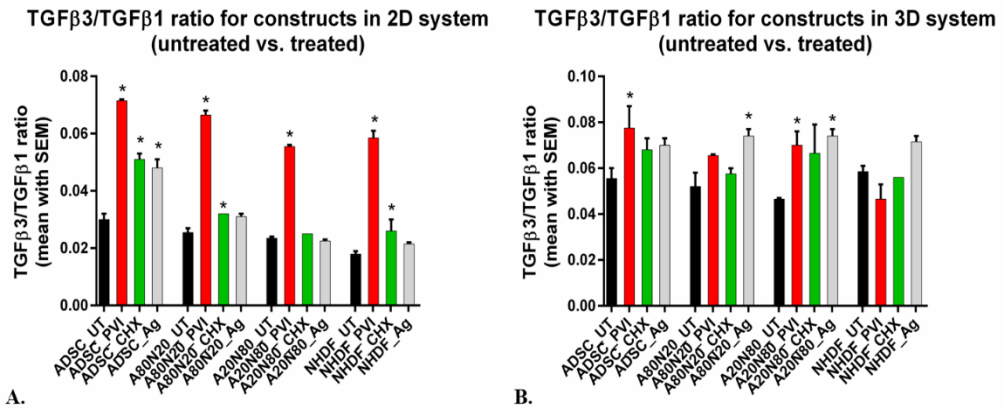

Fig. 2. TGFβ3/TGFβ1 ratio following treatment: A. Constructs in 2D system – The ratio increases significantly following PVI treatment for all cell condition and the variation pattern follows the stem cell ratio. TGFβ3/TGFβ1 ratio is significant following CHX treatment in monocultures and A80N20 condition (*$p < 0.0001$, R^2 0.9900; CI 95%); B. Constructs in 3D system – TGFβ3/TGFβ1 ratio shifts: significant differences following PVI for ADCS and A20N80; following Ag only for co-cultures. (*$p < 0.0001$, R^2 0.9900; CI 95%).

When TGFβ3/TGFβ1 ratio is compared for the same untreated cell condition in 2D culture system vs. 3D culture system, it is increased significantly in 3D cultures. For stem cell monocultures, although the ratio increases following treatment more in 3D cultures than in 2D cultures, it is significant only following Ag exposure ($p < 0.001$, R^2 0.914) (Fig. 3A). Following CHX and Ag treatment, TGFβ3/TGFβ1 ratio increases for fibroblasts ($p < 0.0001$, R^2 0.9731) and co-cultures ($p < 0.0001$, R^2 0.9771 for A80N20 and $p < 0.0002$, R^2 0.9429 for A20N80) more in 3D cultures (figs. 3C-D). Following PVI treatment, in all cell conditions the TGFβ3/TGFβ1 ratio shifts are minimal, with no statistical significance between the two culture systems.

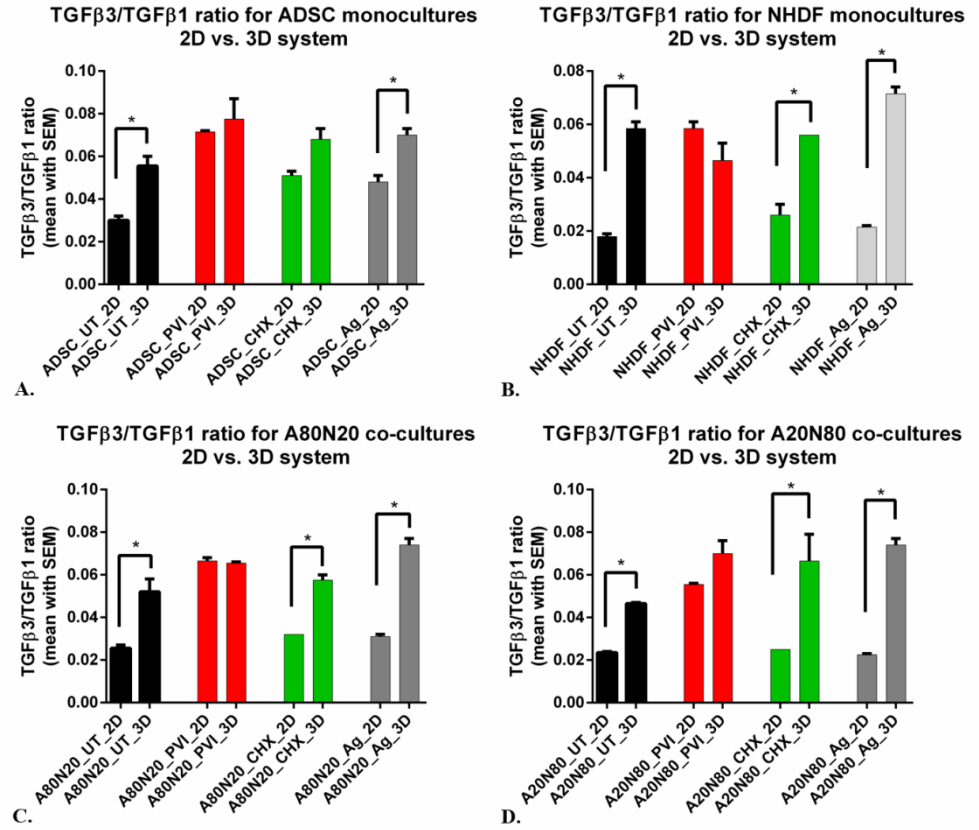

Fig. 3. TGFβ3/TGFβ1 ratio comparison between 2D and 3D culture systems: A. ADSC monocultures - Ratio is more increased for untreated and following Ag exposure in 3D culture system (*$p < 0.001$, R^2 0.914; CI 95%); B. A80N20 co-cultures – TGFβ3/TGFβ1 ratio increases significantly following CHX and Ag treatment for 3D culture conditions (*$p < 0.0001$, R^2 0.9771; CI 95%); C. A20N80 co-cultures – TGFβ3/TGFβ1 ratio has similar pattern as in A80N20 condition, with differences for CHX and Ag treatment in 3D cultures (*$p < 0.0002$, R^2 0.9429; CI 95%); D. NHDF monocultures – As in co-cultures, TGFβ3/TGFβ1 ratio is more increased for 3D culture systems following CHX and Ag treatment (*$p < 0.0001$, R^2 0.9731; CI 95%)

DISCUSSION

Currently there are no global guidelines in regards with antiseptics and wound care, although chronic wounds and burns can be clinically challenging (1, 6, 14). Critical colonization and wound infection impair the healing process, thus aside wound healing promotion, obtaining bioburden control is a critical point towards proper wound healing (3). An antiseptic should have an effective antimicrobial activity with a minimal cytotoxicity (1). Some studies suggest that that antiseptics promote healing by the sole control of bacterial load, although there is emerging data that they may promote wound healing by other mechanism as well, including cytokine modulation (4, 7, 15). Current available data regarding antiseptics cytotoxicity and possible drawbacks on wound healing is controversial and heterogeneous. Moreover, there is a lack of standards in evaluation, both regarding research and clinically, that makes it difficult to develop management guidelines (2, 4, 16).

Povidone-iodine is one most used antiseptics, as wound dressings, ointments, or irrigation/cleansing, although the data regarding efficiency and adverse effects is conflicting (1, 6, 15). Wang *et al*. reported that topical application of 0.5% PVI on post excisional full thickness wounds in rats promote αSMA and TGFβ expression and enhanced healing process (7). Murine wound healing is mainly through wound contraction, compared with granulation tissue formation and reepithelization (17). Moreover, it seems that murine fibroblasts tolerate better PVI compared with human fibroblasts (12). Fumal *et al*. compared topical PVI with CHX and silver sulfadiazine in chronic leg ulcers management and reported that PVI increased the healing rate and did not significantly affect fibroblast (14). Regarding PVI effects on ADSC, there are limited reports. Kim *et al*. evaluated PVI effects on freshly isolated ADSC and they reported that PVI decreased proliferation and differentiation rates, promote necrosis and down regulated stem cell markers (18). The results presented suggest that PVI may modulate cytokines expression, by increasing TGFβ3/TGFβ1 ratio in both 2D and 3D cell culture systems. Although, the data also reveals that this is dependent also on cell types and construct conditions.

Although, alcohol-based chlorhexidine is superior to PVI for preoperative cleansing, data regarding CHX effects on wound healing is limited. It is an antiseptic used for wound irrigation, mainly burns and oral cavity (6, 19, 20). Park *et al*. reported that CHX decreases viability of cultured stem cells isolated from buccal fat pad (21). Pilloni *et al*. evaluated CHX effects on human gingival tissue and concluded that it promotes a "scar wound healing response" by increasing αSMA expression (20). Herein, following CHX treatment TGFβ3/TGFβ1 ratio increased, although with statistical significance difference only in some cell conditions cultured in 2D systems.

Silver nanoparticles bring new and particular properties, including through anti-inflammatory effects, decreasing cytokine release and wound healing efficacy (4). Mainly used in chronic wound and burn management, the available data in regards with Ag is diverse (1, 2). Lin *et al*. obtained better healing with faster wound reduction when using Ag, compared with gauze (3). Tian *et al*. evaluated Ag effects on a thermal injury model in rats and reported that TGFβ1 had a peak at day 3 following injury, followed by a decreased and maintained low level in the wound area treated with silver nanoparticles. Moreover, they suggested a better cosmetic outcome (8). Herein, the effect of Ag treatment was

more pronounced on 3D culture conditions, increasing significantly TGFβ3/TGFβ1 ratio on co-cultures, suggesting that silver nanoparticles within the dressing modulate TGFβ levels. Nešporová *et al*. shown that wound dressings containing silver display toxicity on ex vivo skin by decreasing viability, inducing oxidative stress and DNA damage (22). Also, regarding Ag effects on stem cells, current data is limited. Hackenberg *et al*. concluded that silver nanoparticles display a cyto- and genotoxic on human mesenchymal stem cells in higher concentrations than levels needed for antimicrobial efficiency (11).

Ex utero healing process implies scar tissue formation; thus, efforts are made towards therapies that improve scars based on fetal healing. TGFβ cytokines are known as key players in wound healing process and as TGFβ1 is associated with scar tissue formation and fibrosis, TGFβ3 has an anti-scaring effect (9, 10). Tyrone *et al*. improved and accelerated fascial wound healing using TGFβ3 delivered in the wound using a methylcellulose vehicle (23). In the present study, although further research is required, the results suggest that antiseptics may have an effect including on scar tissue formation, by modulating the TGFβ3/TGFβ1 ratio.

Furthermore, although 2D monolayer cultures are widely used, cost-efficient and simple, 3D cultures provide a cell microenvironment closer to in vivo setting by adding the architectural cell arrangement. Thus, in 3D culture settings, cells display a phenotype closer to in vivo cellular responses (24). Herein, regarding TGFβ3/TGFβ1 ratio, there are differences on cytokine levels between 2D and 3D culture systems, for both treated and untreated conditions.

CONCLUSIONS

TGFβ3/TGFβ1 ratio pattern modulation *in vitro* is dependent on antiseptic, cell type, cell ratio and culture system. Although the data suggests that antiseptics may improve scar tissue formation, further research is required. Moreover, based on the differences displayed between cell types and cell culture conditions and diverse current published data, results are difficult to translate in clinical settings. Thus, standardized methods for antiseptic testing and evaluation should be developed to facilitate data extrapolation into clinical wound management guidelines.

PLASTIC SURGICAL TECHNIQUES FOR THE TREATMENT OF BURN ABNORMAL SCARS IN PEDIATRIC PATIENTS (Abstract): Post-burn scars have a major impact on the quality of life of pediatric patients, both from a psychological and functional point of view. Pediatric patients with post-burn scars usually have difficulties integrating into the collective due to the low self-esteem determined by the poor aesthetic outcome of the deep or large burns. From a functional standpoint, burn contractures are a significant cause of disability in burn survivors worldwide, as they can affect the tendons and muscles or impair joint mobility. The statistical information that results from this study plays a role in improving the therapeutic protocol. The reconstruction methods of post-burn abnormal scars can be used in order to prevent or to treat the psychological consequences and the functional disability of the affected segment. **Material and methods:** The study includes a group of 147 patients aged between 1-24 years, male and female, admitted through the emergency or outpatient service in the Department of Plastic Surgery and Reconstructive Microsurgery in the "Sf. Maria" Emergency Children Hospital Iasi. **Results:** From the total number of pediatric patients with post-burn scarring sequelae (n=147), 32.65% (n=48) were treated by local triangular skin flaps plasty, 18.36% (n=27) by full-thickness skin graft plasty, 12.92% (n=19) by scar excision and suture, 11.56% (n=17) by tissue expander implant, 7.48% (n=11) by employing the Z-plasty technique, 5.44% (n=8) by associating a local triangular skin flap with a full-thickness skin graft, 5.44% (n=8) by combining Z-plasty with a full-thickness skin graft, 2.04% (n=3) benefited from plasty with synthetic dermis (Integra®), 1.36% (n=2) were treated by degranulation, 1.36% (n=2) by Triamcinolone injection, less than 1% (n=1) of patients received dermabrasion or hair transplantation. **Conclusions:** Skin flaps represent the most effective and frequently utilized method of treatment of post-burn scar sequelae. **Keywords:** BURNS, HYPERTROPHIC SCARS, KELOID SCARS, SKIN FLAPS, SKIN GRAFTS, EXPANDER, Z-PLASTY.

Burns represent one of the most frequent causes of accidental injuries and are a life-threatening and potentially disabling pathology with major psychological and social implications.

The essential therapeutic objectives are

the survival of the patient, prevention of complications of the acute phase, preservation of the functions of the affected segments, an acceptable cosmetic result, and limitation of psychological trauma (1). Approximately 90% of burns in pediatric patients occur at home, while in adolescents there is a higher rate of occurrence outside of the home (2). An accurate assessment of the extent of burns is critical because resuscitation efforts are based on the affected body surface area. Overestimating or underestimating the surface area of burns can lead to therapeutic failure. Computer applications such as the SAGE chart can provide more accurate assessments (3).

There are multiple methods used for treating burn injuries: skin grafting combined with negative pressure therapy, skin flaps, tissue expanders, artificial dermis, and stem cell therapies. Management practices regarding burn wound healing include initial wound assessment, debridement, dressing, and reconstruction with primary or secondary closure, skin grafts or flaps (4, 5). Skin grafts are divided into 4 categories: autograft, allograft, xenograft, and artificial skin (6). Skin flaps differ from skin grafts by their mobilization along with preserving the vascular source (5). A flap may comprise skin, skin and muscle, muscle and bone, or various combinations of tissues. Flap techniques are based on the local angiosome vascular anatomy (7). Tissue expander reconstruction was originally used for breast reconstruction, but later found utility in the reconstruction of excisional defects resulting from a variety of causes, including postburn surgery. The tissue expander is a silicone balloon with an injection port that allows the injection of a saline solution that will increase its volume and consequently expand the healthy adjacent tissue (8). Compared to other techniques, such as skin grafting or flap transfers, tissue expansion allows a better match of skin color and texture, in addition, to preserving hair follicles and sensory nerves (9, 10). In terms of artificial dermis utilized in post-burn sequelae treatment, there are several types such as Integra®, Matriderm®, or Pelnac® (11, 12, 13).

The aim of this study is to highlight the modern methods of treatment of post-burn sequelae and to improve therapeutic conduct to prevent psychological trauma and functional impotence of the affected segment.

MATERIAL AND METHODS

The study includes a group of 147 patients aged between 1-24 years, male and female, admitted through the emergency or ambulatory service in the Department of Plastic Surgery and Reconstructive Microsurgery in the "Sf. Maria" Emergency Children Hospital from Iași, between the years 2010-2020, most of which were admitted repeatedly. Data was collected from observation charts from the hospital's archives and the patient's attending physicians. The collected data comprised of date of birth, age, sex, living conditions, history of burns, and surgical therapeutic plan to which was added information from the observation protocols for patients during the hospital stay and periodical surgeries that were performed. Also, the study was carried out respecting ethical norms, by protecting the confidentiality of the information and the anonymization of the patients in the database. All patients benefited from paraclinical explorations consisting of collecting the usual analyses: complete blood count, inflammatory markers (ESR,

CRP), urea, creatinine, blood glucose, transaminases, exploration of hydro electrolytic and acid-base metabolism, urine summary, coagulation tests, blood group, Rh and imaging studies such as lung X-ray to identify the presence of disorders that may delay surgical intervention and their correction. Moreover, in the morning before surgery, an intensive care physician performed a full pre-anesthetic check-up to assess the anesthetic-surgical risk.

RESULTS

The incidence of hypertrophic scars at 86% (n=127) is six times higher compared to that of keloid scars at 14% (n=20) (fig. 1).

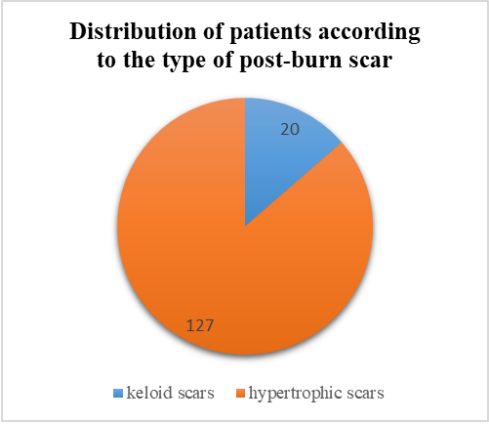

Fig. 1. Distribution of patients according to the type of post-burn scar

From the total number of pediatric patients with post-burn scarring sequelae (n=147), 32.65% (n=48) were treated by local triangular skin flaps plasty, 18.36% (n=27) by full-thickness skin graft plasty, 12.92% (n=19) by scar excision and suture, 11.56% (n=17) by tissue expander implant, 7.48% (n=11) by employing the Z-plasty technique, 5.44% (n=8) by associating a local triangular skin flap with a full-thickness skin graft, 5.44% (n=8) by combining Z-plasty with a full-thickness skin graft, 2.04% (n=3) benefited from plasty with synthetic dermis (Integra®), 1.36% (n=2) were treated by degranulation, 1.36% (n=2) by Triamcinolone injection, less than 1% (n=1) of patients received dermabrasion or hair transplantation (tab. I).

TABLE I

Distribution of patients according to the surgical intervention of postburn scar sequelae

Type of surgery	Cases
Dermabrasion	1
Hair transplant	1
Degranulation	2
Triamcinolone injection	2
Synthetic dermis	3
Combination of skin flap and skin graft	8
Combination of Z-plasty and skin graft	8
Z-plasty	11
Expander implantation	17
Scar excision	19
Skin graft	27
Triangular skin flap	48

In fig. 2, we note that 45% (n=9) of the patients diagnosed with keloid scars benefited from local triangular skin flap plasty. This indicates that this method of treatment for post-burn keloid scars is both commonly used and very effective. And even though the patient group is scant and poses low statistical significance, it still confirms the hypothesis that skin flaps are the most used method of reconstruction of post-burn scar sequelae. Also, 20% (n=4) of these patients were treated by scar excision and suture, 10% (n=2) by full-thickness skin graft plasty, another 10% (n=2) by tissue expander implantation, 5% (n=1) by combining Z-plasty with a full-thickness skin graft.

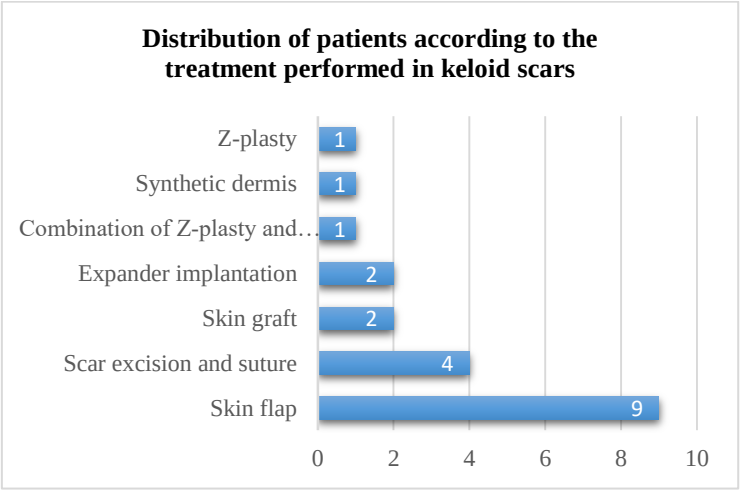

Fig. 2. Distribution of patients according to the treatment performed in keloid scars

The graphic representation in fig. 3, illustrates that 31.49% (n=40) of the patients diagnosed with hypertrophic scars benefited from a local crossed triangular skin flap plasty. This result confirms the previously presented idea: skin flaps are the most used method for the reconstruction of post-burn scar sequelae because they maintain their vascular source with mobilization, unlike skin grafts that are avascular and require a well-vascularized wound bed.

In figures 4 and 5, the pictures describes a case of post-burn syndactyly at 3/4 fingers and a case with retractable hypertrophic post-burned cervical scar, both treated with local flaps.

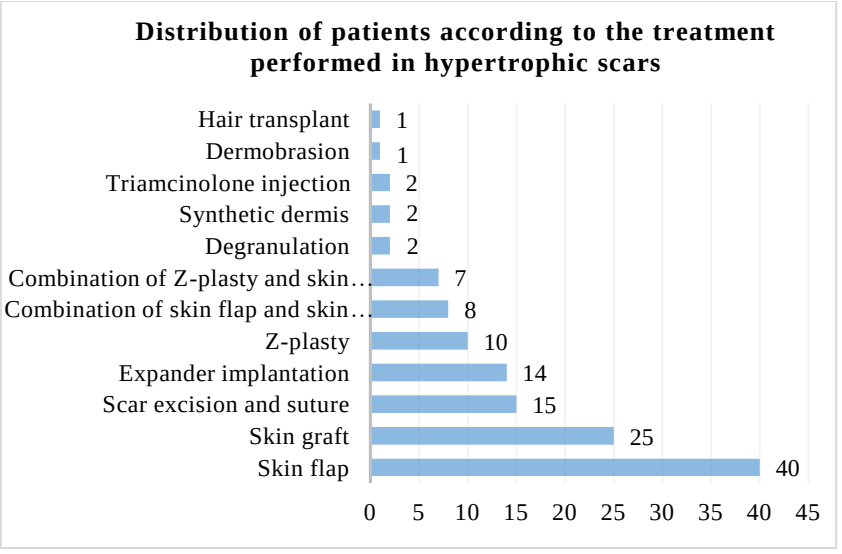

Fig. 3. Distribution of patients according to the treatment performed in hypertrophic scars

Fig. 4. Post-burn syndactyly at 3/4 fingers

Fig. 5. Retractable post-burn hypertrophic scar

Also, 19.68% (n=25) of the patients diagnosed with postburn hypertrophic scars benefited from full-thickness skin graft plasty, 11.81% (n=15) from scar excision and suture, 11.02% (n =14) of implantation with an expander, 7.87% (n=10) of Z-plasty, 6.29% (n=8) from a combination of skin flap with a skin graft, 5.51% (n=7) Z-plasty and skin graft association, under 2% of the patients benefited either from scar degranulation, artificial dermal substitute (Integra®), Triamcinolon injection, dermabrasion or hair transplantation.

It is observed that 45% of patients diagnosed with post-burn keloid scar sequelae benefited from treatment with crossed triangular skin flaps and 10% from skin grafting, as a result, the most common method of skin plasty is flap plasty with a flap:graft ratio of 4.5:1. This difference was found to be statistically significant (p=0.03). Also, 31.5% of patients diagnosed with hypertrophic scar benefited from plasty through crossed triangular skin flaps, as opposed to 19.7% of patients who benefited from plasty with skin graft, with a flap:graft ratio of 1.6:1. This difference was found to be statistically significant (p=0.03).

DISCUSSION

We observe in the results of our study that the most common post-burn scar sequela developed in pediatric patients is the hypertrophic scar with a percentage of 86% (n=127) of the total number of patients included in the group (n=147), followed by the keloid scar with a percentage of 14% (n=20), hypertrophic scar: keloid ratio of 6.35:1. This confirms the involvement of the genetic factor in the pathogenesis of keloid scars, according to the study by Gurtner *et al.* in 2018 in which he specifies that keloid scars occur more frequently in pigmented individuals and in African populations. These types of sequelae produce patients with functional impotence if the burn is located at or near a joint. Atrophic scars are not present in our group of patients because this type of scar occurs more frequently after a trauma, and less often due to post-burn (7).

Since the intention of this study is to discover the modern methods of treatment for post-burn scar sequelae in pediatric patients, the initial distribution of patients had to be made according to the treatment

method used. Later, they were divided into two diagnostic groups (post-burn keloid scar sequelae, respectively post-burn hypertrophic scar sequelae) to find which treatment method was more frequently used depending on the type of scar. Thus, we observed that the most used and effective treatment method in both types of scar is the use of the local triangular crossed skin flap, from which 32.65% of patients (n=48) benefited.

Our results are consistent with the systematic review of free tissue transfers in burns by Shehab Jabir *et al.* in 2014 which included 30 studies conducted between 1984-2012 stating that free flaps can play an essential role in primary reconstruction as well as secondary reconstruction in burn patients. When used in primary reconstruction, they can significantly reduce the length of hospital stay, and the number of operations to achieve wound closure and, in some cases, even save limbs that would otherwise have to be amputated. When used in secondary reconstruction, they may be the only way to provide the necessary amounts of tissue to achieve sufficient release of the contracture, close chronic wounds, and treat unstable scars. This translates into reduced morbidity and improved functionality and aesthetics for patients (14).

Also, in our group of patients, 18.36% (n=27) benefited from a full-thickness skin graft. This type of plasty is most frequently used in acute skin burns with defects spanning a large surface area. There is no evidence that full-thickness skin grafting is clearly superior to split skin grafting for covering palmar burns according to the meta-analysis by Theddeus *et al.* in 2015. The current trend is to use FTSG as a wound dressing for hand burns in children because it is believed to have a lower rate of secondary contracture and it could decrease the need for the secondary reconstructive procedure; however, FTSG has some limitations in its use. FTSG has limited donor sources, so it cannot be used to cover large burn areas. It also has a lower absorption rate compared to STSG due to edema and inflammation reactions. STSG also has some disadvantages, such as a higher rate of secondary contracture and a relatively lower aesthetic value. However, using STSG is advantageous in that it can cover a large area (15). It can also be combined with artificial dermis like Integra or Matriderm for a better functional result (16, 17, 18). The scientific literature states the existence of 3 methods of fixing the skin graft: stapler, cyanoacrylate adhesive, and tie-over dressing. The tie-over dressing is the traditional technique that no longer always provides satisfactory results in some areas of the body (19). Pediatric patients with post-burn cicatricial sequelae in which skin grafting was performed as a method of healing also benefited from VAC treatment because an improvement in the healing rate and a decrease in the wound infection rate was observed. This result is consistent with the randomized controlled trial conducted by Zheng XP *et al.* in 2019 in the Department of Burn Surgery of the First Affiliated Hospital of the University of Naval Medicine (20).

According to our results, 11.56% (n=17) of the patients benefited from tissue expansion with the help of an expander. Unlike other treatment techniques, such as skin grafting or the use of skin flaps, tissue expansion allows for a better match of skin color and texture (8, 21). The number of patients who have benefited from this method of skin plasty is reduced because following the presentation to the parents by

the attending physician of the available skin plasty methods, respectively their advantages and disadvantages, the parents were much more reluctant to choose the skin expander as a treatment method.

The conservative methods to prevent abnormal scarring, the long-term follow-up of the scars along with intense kinesitherapy are extremely important (22, 23). There is a possibility to treat the burn wounds in the acute phase and as well in the late reconstruction with skin substitutes, along with intermittent fat grafting of the scar (11, 24, 25).

CONCLUSIONS

Burns are a serious health problem, especially in low-income countries. They cause many deaths each year and are the leading cause of disability in many countries. Post-combustion contractures on extremities present a clinical challenge. Flexion contractures are more common than extension contractures. In mild contractures (defined simply as more than 50% of the range of motion of the joint is still possible), plastic surgical techniques, for example, the Z-plasty technique can be used to elongate the scar by transposition of the adjacent normal tissue. In more severe cases, there is not enough adjacent tissue to allow contracture elongation and a different surgical approach is required. The most used and effective method of treatment in both types of post-burn scar sequelae is the use of the skin flap. This method is followed by scar excision and suture in the case of keloid scars, respectively by full-thickness skin graft plasty used in the case of hypertrophic scars.

Compared to skin grafts, flaps have the ability to expand to allow full extension of the affected region. Flaps are essential reconstructive modalities frequently used by plastic surgeons. As techniques evolve, many varieties of tissue transfer appear. A thorough understanding of the underlying principles, the ability to apply them to specific situations, and careful assessment of patient needs are necessary for the successful use of this tool. Recent advances in burn reconstruction offer methods to reduce scar tissue and joint contractures.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

EPIDEMIOLOGY OF CHRONIC KIDNEY DISEASE AND COMORBID ILLNESS IN HOSPITALIZED GERIATRIC PATIENTS (Abstract): **Background and aims**: The number of older people in Europe is expanding. Although chronic kidney disease (CKD) becomes more common with increasing age, data concerning epidemiology of CKD in older people are scarce, especially in Eastern Europe countries. In the current analysis, we aimed to fill the gap on CKD epidemiology in older people from Romania, by describing a large population of hospitalized geriatric patients. **Material and methods:** In this retrospective cohort study we included all patients aged ≥ 65 years hospitalized in the Geriatric Department of "Dr. C. I. Parhon" Hospital from Iași, Romania, between 2012 – 2022. CKD was identified as decreased estimated glomerular filtration rate (<60 mL/min/1.73 m^2) according to CKD-EPI equation. Investigated comorbid conditions included diabetes mellitus, hypertension/hypertensive heart disease, coronary artery disease, congestive heart failure, atrial fibrillation, chronic respiratory failure and anemia. **Results**: 3,563 geriatric patients (59.2% females) were hospitalized between 2012-2022. 3116 patients (87.4% of the total population) had a serum creatinine assay. Among these patients, the prevalence of CKD using the CKD-EPI equation was 38%. We found an unequal annually distribution between the number of patients with a diagnosis of CKD according to electronic health records and the number of patients with estimated glomerular filtration rate (eGFR) < 60 mL/min/1.73 m^2. 86,7% of the patients with eGFR < 60 mL/min/1.73 m^2 had at least 2 comorbidities. Only 2,4% of the patients with eGFR < 60 mL/min had no other chronic condition. **Conclusions:** In Romanian older hospitalized patients, the prevalence of individuals with eGFR <60 mL/min/1.73 m2 is higher than previous reports from our country. In geriatric adults, CKD is not an isolated entity, and the burden of cardiovascular comorbid illness is high. **Keywords**: EPIDEMIOLOGY, CHRONIC KIDNEY DISEASE, COMORBID ILLNESS, HOSPITALIZED GERIATRIC PATIENTS.

The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines define chronic kidney disease (CKD) as abnormalities of kidney structure or function, present for > 3 months, with implications for health (1). The classification of CKD requires the determination of the cause of CKD, glomerular filtration rate (GFR) category (G1-G5) and albuminuria category (A1-A3). By standardizing the definition and staging of CKD, data on CKD burden have grown. Globally, in 2017, there were 697.5 million

cases of all-stage CKD, for a global prevalence of 9.1 % (2). However, based on a meta-analysis of 100 studies (roughly 7 million patients), the global CKD prevalence could be as high as 13.4 %, with a prevalence of CKD stages G3 to G5 of 10.6 % (3). In Europe, estimates of CKD prevalence indicate a regional variation across 27 countries that ranges from 3.31% in Norway to 17.3 % in Germany (4). Regional disparities in CKD burden arise from differences in geographic area and ethnicity, issues related to GFR estimation (e.g., type of equation used) ore one-off testing assessments in large-scale reports.

Although the growing CKD burden parallels the expanding proportion of older individuals, data concerning epidemiology of CKD in older people are scarce, especially in Eastern Europe countries. These patients have multiple chronic conditions that need to be correctly quantified for guiding risk stratification and subsequent management. Previously, European Renal Best Practice (ERBP) guidelines shed some light on management of older patients with advanced CKD, by stimulating implementation of validated tools for predicting the most important risks, death and progression to end-stage renal disease (ESRD). When comparing the above - mentioned risks, it is important to note that in older people with CKD, death is a more likely event than progression to ESRD, even at severe reductions in GFR (5).

The starting point for an effective strategy of screening for CKD consists of increasing awareness of the true burden of the disease and utilization of simple laboratory tests (serum creatinine to estimate GFR and proteinuria) to identify CKD in people at risk. A systematic review suggested that screening for CKD is cost effective in people with diabetes and hypertension, the two most common causes of CKD worldwide (6). From a practical point of view, early identification of CKD in people at-risk is beneficial in the primary care settings if the programs are associated with treatment strategies. However, there are no current evidence-based recommendations regarding the frequency of screening in people at risk of CKD.

In the current analysis, we aimed to fill the gap on CKD epidemiology in older people from Romania, by describing a large population of hospitalized geriatric patients. We found only two other analysis (7, 8) published in that last twelve years that investigated the prevalence of CKD in the adult population of Romania, none with focus on geriatric patients.

MATERIAL AND METHODS

In this retrospective cohort study, we included all patients aged ≥ 65 years hospitalized in the Geriatric Department of "Dr. C. I. Parhon" Hospital from Iasi, Romania, between 2012 - 2022.

This Geriatric Unit covers the entire North-East region of the country, so patients are representative for a population of almost 4 million people. We selected for our analysis those in which serum creatinine was performed. In this population, we calculated the estimated glomerular filtration rate (eGFR) by using CKD-EPI equation. Based on the KDIGO definition and classification of CKD (1), we first divided our population into "no CKD" (defined as eGFR > 60 mL/min/1.73 m2) and "CKD" (eGFR < 60 mL/min/1.73 m^2). The CKD group was further classified based on GFR category in G3a (45-59 mL/min/1.73 m^2),

G3b (30-44 mL/min/1.73 m^2), G4 (15-29 mL/min/1.73 m2) and G5 (<15 mL/min/1.73 m^2). Investigated comorbid conditions included diabetes mellitus, hypertension/hypertensive heart disease, coronary artery disease, congestive heart failure, atrial fibrillation, chronic respiratory failure and anemia. We investigated the distribution of these comorbidities in the entire geriatric population and in the CKD group.

RESULTS

In the Geriatric Unit from "Dr. C. I. Parhon" Hospital from Iasi between 2012 and 2022, there were 3,563 patients hospitalized with an age greater than 65 years old at admission - 1,453 (40.8%) male, 2,110 (59.2%) female.

Out of the total patients > 65 years old (3,563), only 3116 patients had at least one serum creatinine value determined between 2012 and 2022 (a total of 7954 values determined). Taking into account the first creatinine value corresponding to an estimated GFR of < 60 mL/min/1.73 m^2 (CKD-EPI), there were 1,187 individual patients with an eGFR <60 mL/min/1.73 m^2, corresponding to a prevalence of 38%. Mean age of patients with eGFR < 60 mL/min/1.73 m^2 was 79 years and gender distribution was unequal (63.4% females).

We explored the distribution of the primary or secondary diagnosis of Chronic Kidney Disease (N18, N19) according to International Classification of Diseases (ICD 10) in the hospital records. The difference in numbers between patients with eGFR < 60 mL/min and patients with CKD (ICD 10) as primary or secondary diagnosis is shown in first figure.

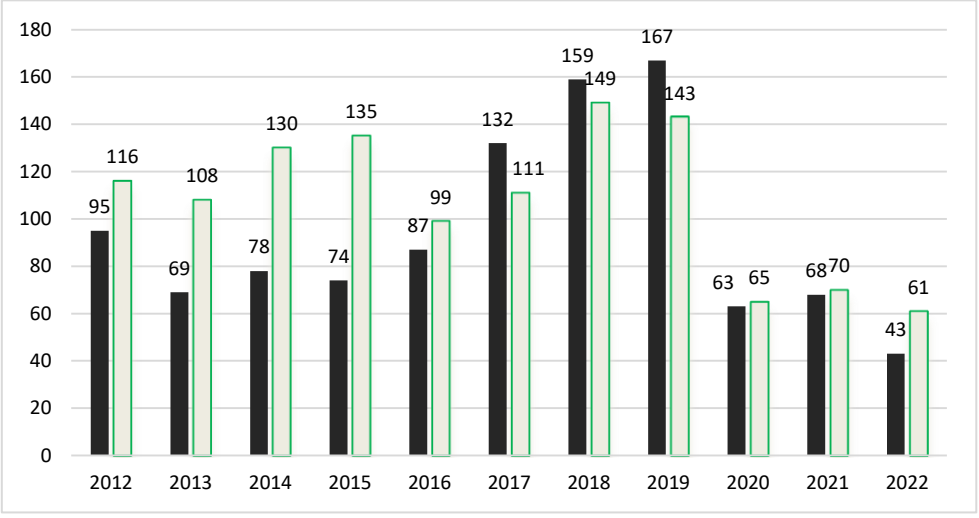

Fig. 1. Number of patients with eGFR < 60 mL/min (white) and patients with CKD diagnosis (ICD 10) (black), between 2012-2022.

Out of the 3,116 patients with at least one serum creatinine assessment, 1,655 patients had 2 or more creatinine values during different hospitalizations. Taking into account the first hospitalization of each patient during the 10-year interval, we found that 758 patients

had an eGFR < 60 mL/min of first assessment in the Geriatric Unit. The distribution of eGFR according to CKD-EPI for the first admission is described in first table.

TABLE I.
The distribution of eGFR according to CKD-EPI for the first admission

eGFR	Women	Men	Total
>90 mL/min	359	382	741
60-89 mL/min	1035	582	1617
45-59 mL/min	284	180	464
30-44 mL/min	163	71	234
15-29 mL/min	35	19	54
<15 mL/min	6		6
Total	**1,882**	**1,234**	**3,116**

According to ICD 10 diagnosis, in patients with eGFR < 60 mL/min, the most frequent comorbidity was heart failure (28.9%), followed by hypertension (20.7%), ischemic heart disease (15.2%), diabetes (10.5%), chronic respiratory disease (7.5%), atrial fibrillation (5.3%) and anemia (6.3%) (tab. II).

The distribution of patients with eGFR < 60 mL/min stratified by the number of comorbidities showed that 86.7% had ≥ 2 comorbidities. The largest CKD subgroup was the one that associated 3 comorbidities (315 patients, 31.5%), followed by two subgroups that had 2 comorbidities (249 patients, 24.9%), respectively 4 comorbidities (189 patients, 18.9%). Only a minority of patients with eGFR < 60 mL/min (24 adults, 2.4%) had no other chronic condition (tab. III).

TABLE II.
Distribution of main comorbidities according to eGFR

Comorbidities	eGFR>=60	eGFR<60	All patients (n= 3,116)
Heart failure	29.60%	28.90%	29.38%
Hypertension	21.10%	20.70%	21.00%
Ischemic heart disease	16.90%	15.20%	16.46%
Diabetes mellitus	8.30%	10.50%	8.90%
Chronic respiratory disease	8.30%	7.50%	8.12%
Atrial fibrillation	5.30%	5.30%	5.30%
Anemia	4%	6.30%	4.64%
Other comorbidities	6.40%	5.60%	6.21%

TABLE III.
The number of concurrent comorbidities in patients with eGFR < 60 mL/min.

Number of concurrent comorbidities	Percent of patients with eGFR < 60
0	2.40%
1	10.90%
2	24.90%
3	31.50%
4	18.90%
5	8.00%
6	2.90%
7	0.30%
8	0.10%

DISCUSSION

The analysis of this representative sample of the Romanian older hospitalized patients shows that the prevalence of eGFR <60 mL/min/1.73 m^2 is high (38 %). The identified prevalence is higher than the one previously reported by Mota *et al.* (8). In that study, researchers analyzed data from 2,717 Romanian adults and found an overall age- and sex-adjusted prevalence of CKD of 6.74%. The prevalence of CKD increased with age from 3.69 % in the 20–39-year age group to 14.35 % in the 60–79-year age group. In the Kidney Early Evaluation Program (KEEP) and National Health and Nutrition Examination Survey (NHANES) in the United States, which included more than 32,000 patients aged at least 65 years, the prevalence of CKD was 44% (9), which is similar to our findings.

In a systematic review of 26 population-based studies, the median prevalence of CKD was 7.2% in people aged ≥ 30 years, but it ranged from 23.4% to 35.8% in people aged ≥ 64 years (10).

An important section of our analysis was the comparison between the number of patients with a diagnosis of CKD according to International Classification of Diseases (ICD 10) and the number of patients with eGFR < 60 mL/min/1.73 m^2, using CKD-EPI equation. This comparison was made for each of the 11 years of the observation period. In the first 4 years of the selected period (2012-2015), there seems to be a greater difference between the CKD diagnosis and patients with eGFR < 60 mL/min/1.73 m^2, with less patients labeled as having CKD (fig. 1). This suggests that there might have been an under-recording of CKD diagnoses in healthcare records. The accuracy of CKD diagnosis using electronic health records (EHR) ultimately depends on the integration and interpretation of data by healthcare providers and the quality of the healthcare system's electronic records.

The difference between the CKD diagnosis and patients with eGFR < 60 mL/min/1.73 m2 is smaller starting from 2016 onward, with a slightly higher number of patients with CKD diagnosis. The number of patients with eGFR < 60

mL/min/1.73 m^2 is constantly increasing until 2019. Since the beginning of the COVID-19 pandemic (2020), both categories of patients are significantly decreased. The main reason could be the significant initial restrictions in the referrals to the Geriatric Unit, followed probably by an increased reluctance for inpatient vs outpatient care in the elderly population.

When examining the number of patients with eGFR < 60 mL/min/1.73 m^2, we can conclude that during the 11-year period, the prevalence has increased from 758/3116 patients (low eGFR on first admission) to 1,187/3,116 patients (taking into account the eGFR progression).

In our study, cardio-vascular pathology was a frequent characteristic of the population, with approximately one third of the patients that have heart failure and one fifth associating hypertension. The extent of the investigated comorbidities was similar across eGFR groups (>/= 60 mL/min *vs.* < 60 mL/min).

We also emphasized that in older adults, CKD is not an isolated entity, which makes the caring for these patients challenging, especially if we add the negative impact of other superimposed geriatric syndromes like frailty and cognitive decline.

CORRELATION BETWEEN OCT MEASUREMENTS AND OXIDATIVE STRESS BIOMARKERS IN PATIENTS WITH AGE-RELATED MACULAR DEGENERATION (Abstract): Age-related macular degeneration (AMD) is a neurodegenerative disease that affects the central retina and is the most frequent cause of irreversible blindness in the elderly population. **Aim:** to establish correlations between functional and structural changes and oxidative stress markers before and after treatment in patients diagnosed with AMD. We wanted to estimate the association of the oxidative stress with the occurrence of age-related macular degeneration. **Materials and methods:** This are a case-control study that included a group of 59 patients diagnosed with age related macular degeneration (23 dry AMD and 36 exudative AMD), and a control group that included 62 patients. They were followed over a period of 12 months by assessment of optical coherence tomography measurements and oxidative stress markers. The oxidative stress markers included superoxide-dismutase (SOD) and thiobarbituric acid reactive substances (TBARS). **Results:** The mean values of SOD and TBARS were significantly higher in the study group compared to the control group. We observed higher values in patients with exudative form of AMD. Even after treatment, the mean values remained higher than in controls. The standard linear regression analysis of the mean retinal thickness values for each individual test, confirmed that the connection between SOD, TBARS and mean retinal thickness meets the requirements of a valid linear regression and SOD and TBARS can be considered to be predictors. Conclusions**:** Increased oxidative stress, which causes oxidative damage to lipids and proteins, may lead to irreversible damage in AMD. Investigating the neuroprotection provided by antioxidants against AMD may be helpful to further entrench the significant role of oxidative stress in AMD. **Keywords**: AGE-RELATED MACULAR DEGENERATION, OPTICAL COHERENCE TOMOGRAPHY, OXIDATIVE STRESS MARKERS.

Age-related macular degeneration (AMD) is a neurodegenerative disease that affects the central retina of elderly patients. This results in a progressive loss of vision, being a common cause of visual impairment in the aging population (1). Based on the disease's clinical and pathological features, there are two subtypes of late AMD: atrophic (dry) and neovascular (wet), both of which can lead to significant visual loss.

Despite the severity of the condition, the etiology and pathogenesis of AMD are poorly understood and current treatment options are not satisfactory (2, 3). The most recent studies point to the key role of oxidative stress in the pathogenesis of AMD (4). Excessive generation of free radicals and other reactive oxygen species (ROS) and imbalance between their generation and the possibility of their degradation by the antioxidant defense system seem to be the most significant factors leading to AMD (5, 6).

The aim of this study is to establish correlations between functional and structural changes and oxidative stress markers before and after treatment in patients diagnosed with age-related macular degeneration. It is also meant to highlight the role of blood markers in early diagnosis of oxidative stress and in early identification of retinal lesions. We wanted to determine whether there is a covariation of the average thickness of the retina and the oxidative stress tests performed in the group of AMD patients, that is, to check whether they can be considered predictors of the variation of the average thickness of the retina.

MATERIALS AND METHODS

This is a case-control study that included a group of 59 patients diagnosed with AMD (23 dry AMD and 36 exudative AMD) and a control group that included 62 patients. Patients with diabetes, inflammatory and infectious diseases or vascular occlusions were excluded. Our inclusion criteria were: the presence of dry and exudative AMD, age between 55-86 years old. All subjects completed a questionnaire confirming the following information: age, gender, non-smoker status, non-consumption of supplements, such as vitamins and antioxidants. In accordance with the patients' rights act, they signed an informed consent. Patients were treated with antioxidant medication and intravitreal injections with antiangiogenic factors - anti vascular endothelium growth factor anti-VEGF - bevacizumab. We included patients that did not have any previous intravitreal IVT injections before enrollment. As for protocols, patients underwent one IVT bevacizumab every month for three months, and after that, one IVT every 2 months.

All patients underwent a comprehensive ophthalmic examination. Choroidal neovascularization CNV was diagnosed by slit-lamp biomicroscopic of the fundus and optical coherence tomography OCT. We measured central retinal thickness-from inner limiting membrane ILM to retinal pigment epithelium RPE, using OCT Spectral OPTOPOL, the Cube scan and Raster scan. The control subjects had a fully normal ophthalmic condition. The follow-up period was for a median of 12 months. Here we include the results at 3 months and 12 months of follow-up. As for oxidative stress markers, we studied the reactive substances of thiobarbituric acid TBARS and antioxidant enzyme - superoxide dismutase SOD. Blood harvested on heparin was taken in the morning. TBARS can be quantified by the colorimetric method. SOD activity, one of the main antioxidant systems in the retina, was determined by the xanthine-oxidase method.

The statistical analysis was intended to highlight significant correlations between the structural and functional changes and the findings of the blood tests. We also wanted to assess the effects of our therapy by comparing data collected before and after treatment. The statistical comparison was drawn using the "difference tests" of the sub-set of descriptive statistic programs; the differences which stood at a safe threshold of 95% ($p < 0.05$) were considered significant.

Another goal was to determine whether there is a covariation of the average thickness of the retina and the oxidative stress tests performed in the group of AMD patients, that is, to check whether they can be considered predictors of the variation of the average thickness of the retina. For this, we studied the statistical relationship between the average thickness of the retina and the oxidative stress tests.

RESULTS

We investigated a group of 59 patients with dry and exudative AMD, 29 men and 30 women, aged between 55-86 years old. We included 23 patients with dry AMD and 36 patients with exudative AMD. The study comprised a control groups (CG) that included 62 subjects, ranging from 53 to 80 years old. The study lasted 12 months. Patients with the exudative form were treated with intravitreal injections with anti-VEGF - bevacizumab, systemic antioxidants, while patients with dry AMD were treated with systemic antioxidants and neuroprotectors, alone or in combination, according to customized treatment plans. We compared the retinal thickness measurements and the blood tests findings before and after treatment.

In the group with neovascular AMD, the mean central retinal thickness decreased continuously and significantly during the follow-up of the patients, from above-normal readings of 420.417 µm on the first examination, to 370.139 µm (p = 0.0002) three months after treatment, reaching a mean value close to the normal reading of 351.083 µm one year after treatment (p = 0.088) (fig. 1).

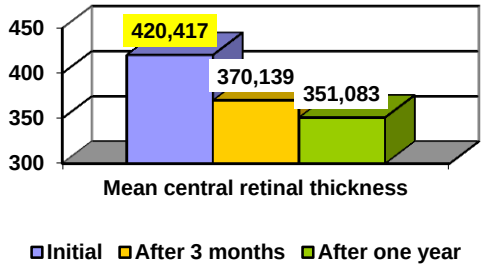

Fig. 1. Evolution of mean central retinal thickness in the neovascular AMD group

A significant reduction in retinal thickness was noted both 3 months and 1 year after treatment. We also noted a decrease in the frequency of edema on the quadrants and on average (fig. 2).

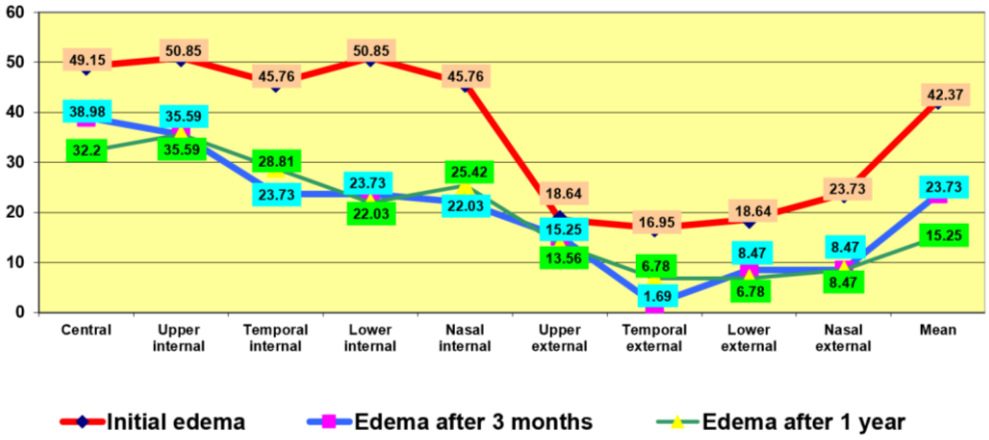

Fig. 2. Frequency of edema before and after treatment

We analyzed the values of SOD and TBARS in patients with dry and wet AMD at baseline and compared them with the control group (tab. I).

TABLE I.

Tests findings in the AMD groups and in the control groups before treatment

Tests	N	Mean	Lowest	Highest	Std. dev.
SOD (U/mL) dry AMD	23	271.91	241.00	296.00	15.46
SOD (U/mL) wet AMD	36	**337.78**	287.00	387.00	25.49
Difference significance (p)	**< 0.00001**				
TBARS (nmols/mL) dry AMD	23	3.95	3.30	4.36	0.26
TBARS (nmols/mL) wet AMD	36	**4.72**	4.13	5.59	0.27
Difference significance (p)	**< 0.00001**				
SOD (CG)	62	**269.55**			13.78
TBARS (CG)	62	**3.91**			0.16

We compared the mean values of SOD and TBARS in patients with dry and exudative AMD, with the mean values of these tests in the control group. We found that the mean value of SOD was significantly higher in patients with exudative form (337.78 U/mL ± 25.49) compared to the dry form (271.91 U/mL ± 15.46, p <0.00001). We also noticed that in patients with exudative AMD the mean value of TBARS was higher (4.72 nmol/mL ± 0.27), compared to the patients with dry AMD (3.95 nmol/mL ± 0.26, p <0.00001). The mean values of SOD and TBARS in the dry form do not differ significantly from those in the control group.

Three months after treatment, the differences of the mean values of the tests were statistically significant. The mean SOD value was significantly higher in exudative AMD patients (319.7 ± 20.8 U/mL) compared to the dry form (261.6 ± 14.5 U/mL, p < 0.00001). Patients with exudative form presented a higher value of TBARS (4.3 ± 0.2 nmol/mL versus 3.7 ± 0.2 nmol/mL in dry form patients, p < 0.00001).

The mean SOD value did no longer show any statistically significant difference one year after treatment. The mean TBARS value was significantly higher in exudative AMD patients (4.2 ± 0.31 nmol/mL), compared with the values in dry AMD (3.69 ± 0.31 nmol/mL, p < 0.00001) (figs. 3 and 4).

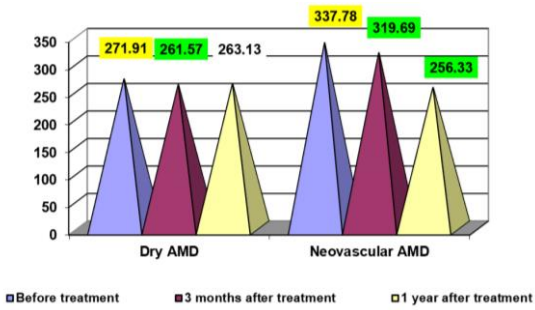

Fig. 3. Mean SOD (U/mL) value

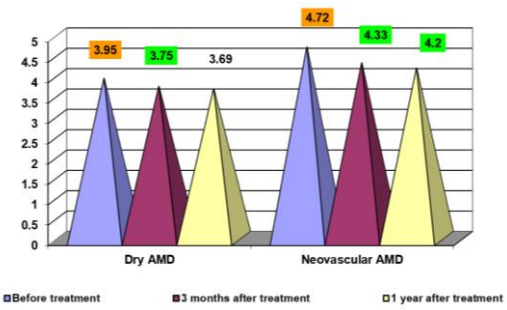

Fig. 4. Mean TBARS (nmols/mL) value

We proceeded to a standard linear regression analysis of the mean retinal thickness values for each individual test (figs. 5 and 6).

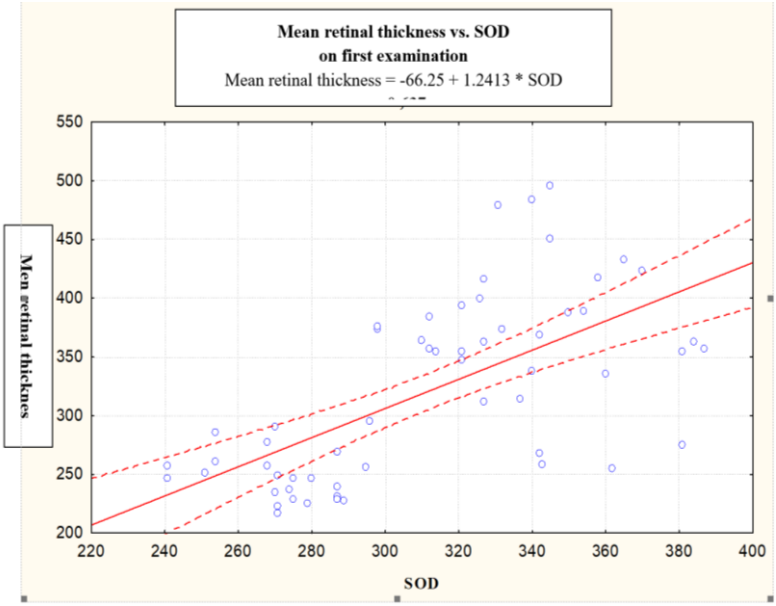

Fig. 5. Regression line of mean retinal thickness in the total group of AMD patients, according to SOD, before treatment

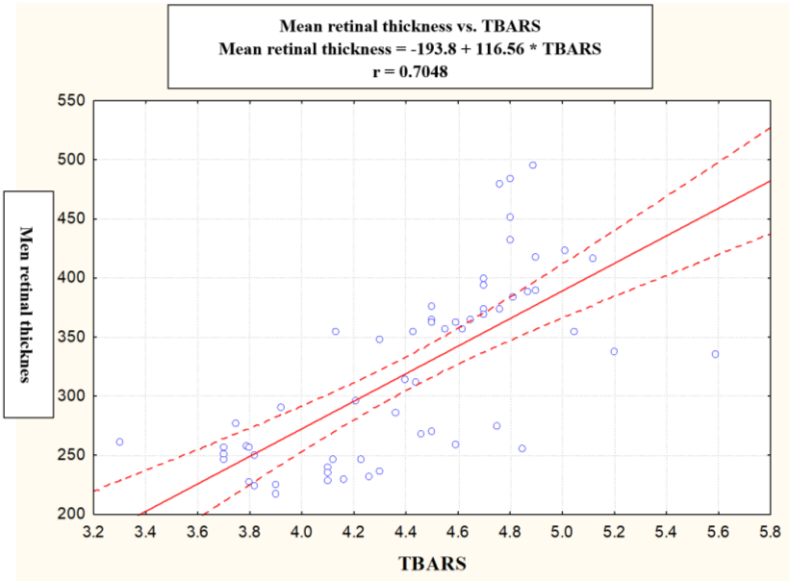

Fig. 6. Regression line of mean retinal thickness in the total group of AMD patients, according to TBARS values, before treatment

The test used to analyze regression is a global significance test of the set of coefficients, *test F* (tabs. II and III).

The fact that the value of the ***F*** test in this case is statistically significant confirms that the relationship between SOD and the mean retinal thickness meets the requirements of a valid linear regression. Therefore, SOD can be considered to be a predictor

TABLE II.

Variance of mean retinal thickness values with SOD values

Effect	Sum of squares	Degrees of freedom	Mean squares	F	P
Regression	**136947.5**	**1**	**136947.5**	**38.92870**	**<0.,0000001**
Residual	200520.7	57	3517.9		
Total	337468.2				

TABLE III.

Variance of mean retinal thickness values with TBARS values

Effect	Sum of squares	Degrees of freedom	Mean squares	F	P
Regression	**167632.1**	**1**	**167632.1**	**56.26029**	**< 0.0000001**
Residual	169836.1	57	2979.6		
Total	337468.2				

As one may notice, before treatment, just like SOD, TBARS may be a mean retinal thickness predictor, perhaps even the best predictor, considering that it has the highest correlation coefficient, r= 0.705.

DISCUSSION

Studies suggested that oxidative stress plays an important role in the pathogenesis of AMD. There is some evidence that oxidative stress and vascular dysfunction may both contribute to the pathology of neovascular AMD (7, 8, 9). Recent studies suggest that the association of oxidative stress, hypoxia and impaired autophagy may be a stimulus for VEGF secretion in RPE cells, thus inducing the appearance of new vessels, the hallmark of exudative AMD (10, 11).

Blood serum from AMD subjects showed increased levels of oxidative stress proven by high malondialdehyde (MDA) levels compared to normal non-AMD cohorts, thus suggesting that systemic oxidative stress is related to AMD (12).

In our research, the mean values of the performed tests did not have a statistically significant difference according to gender in any examination. The mean SOD value decreases significantly three months after treatment in patients with dry AMD - 271.91 U/mL to 261.57 U/mL. Three months after treatment, as well as 12 months after treatment, the mean SOD value is significantly lower in exudative form of AMD (319.69 U/mL and 256.33 U/mL).

According to previous studies, the plasma MDA levels were higher in AMD patients than in controls (13, 14, 15, 16). The more intense SOD activity may be related to higher MDA levels, as a compensatory regulation in response to oxidative stress in AMD patients. SOD lowers the superoxide level, trying to maintain the balance between antioxidants factors and free radicals. Dong *et al.* used a murine model deficient in SOD1 to study how a compromised antioxidant defense system could create a pro-angiogenic environment, and observed that deficient Sod1 mice had a significantly lower expression of VEGF and more neovascularization (17). A systematic review and meta-analysis, involving twelve case-control studies with a total of 634 AMD patients and 656 controls without AMD, concluded that there is some evidence of higher levels of MDA in AMD patients compared to healthy controls (18).

In their murine model designed to study the effects of oxidative stress on retinal tissues, Kim *et al.* noted the progressive accumulation of activated microglia and inflammatory cells in the subretinal space, followed by the appearance of new vessels, along with a significant increase in VEGF levels in RPE cells (19).

Joe Hollyfield identified modified proteins and products of carbohydrate oxidation in drusen composition. Carboxyethyl pyrrole products were identified in drusen, being much more frequent in AMD patients compared to healthy subjects (20). Protein oxidation is also a useful marker for in vivo oxidative stress assessment.

Even if TBARS is an early marker of oxidative stress, it was less studied in relation to AMD. In our study, we found significantly higher values of TBARS in patients with AMD, compared to the values found in the control group. The mean value remained higher after three months of treatment, compared to the control group. By comparing the TBARS mean value in the beginning of the study with the one after treatment in the total study group, we noticed that TBARS mean value decreased significantly. After treatment, the mean TBARS value showed a significantly lower level in patients with exudative form.

We assumed that there is a relationship between AMD and oxidative stress. Therefore, we carried out the standard linear regression analysis of the mean retinal thickness values for each individual test, SOD and TBARS, which confirmed that the connection between SOD and mean retinal thickness meets the requirements of a valid linear regression and SOD can be considered to be a predictor. There is a significant positive correlation between the mean retinal thickness and SOD and TBARS values. Following treatment, the relationship between oxidative stress and the change in retinal thickness diminishes, the effect of the treatment on the reduction of oxidative stress leading to a reduction of its negative influence. This study reveals the need to monitor the progression of AMD patients by assessing oxidative stress markers, alongside OCT.

Anti-VEGF agents are currently the standard of care for exudative AMD, but their role against oxidative damage has been poorly researched. The Polish National AMD Therapeutic Program estimated the approximate need for treatment in a given community to be 0.55-0.66% (21). In a recent study, the authors examined the effects of aflibercept and ranibizumab on in vitro oxidative stress on cultured ARPE-19

cells. In the presence of oxidative stress, these anti-VEGF were able to reduce nitric oxide release induced by H_2O_2 (22). Sheu *et al.* suggested that anti-VEGF agents could be protective in mitochondria, preserving their energetic metabolism, and might reduce cell damage caused by oxidative stress (23). De Cilla *et al.* showed that both aflibercept and ranibizumab inhibited the release of nitric oxide and ROS induced by H_2O_2 and modulated the activation and expression of nitric oxide synthase NOS eNOS and iNOS isoforms in RPE cells (24).

CONCLUSIONS

The results of this study suggest that an impaired antioxidant defense system and increased oxidative stress may play a role in the pathogenesis of AMD. In conclusion, increased oxidative stress, which causes oxidative damage to lipids and proteins, may lead to irreversible damage in AMD. Investigating the neuroprotection provided by antioxidants against AMD may be helpful to further entrench the significant role of oxidative stress in AMD as existing literature is inconclusive. Further research is needed to study new treatments, with the purpose of better counteracting the damaging effect of oxidative stress in AMD.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

COMORBIDITIES OF AUTOIMMUNE BULLOUS DERMATOSES IN NORTH-EASTERN ROMANIA (Abstract): Autoimmune bullous dermatoses (ABDs) are associated with a variety of systemic comorbidities, determined either by skin pathology or by the effects of systemic corticosteroid treatment. The most important comorbidities encountered in autoimmune bullous dermatoses belong to the cardiovascular, neurological, psychiatric, metabolic or infectious sphere. **Materials and methods:** We performed a retrospective observational study used the Minimum Basic Data Set of hospital discharges to review records of patients admitted to Sf Spiridon Iasi public hospital between 2015 and 2019 with a diagnosis of any autoimmune bullous disorder. The objectives were to describe the triggering factors and the comorbidity profile of patients with autoimmune bullous dermatoses. **Results:** The study included 225 patients, the most common autoimmune bullous dermatosis being pemphigus vulgaris. Some comorbidities, diabetes mellitus, or high blood pressure are more often found in patients with bullous pemphigoid, while vulgar pemphigus is more commonly associated with other diseases of autoimmune etiology (autoimmune thyroiditis, vitiligo). **Conclusions:** Evaluation of triggering factors and comorbidities before starting treatment may assist in controlling the disease more swiftly and reducing the side effects of treatment in the management of ABDs. **Keywords:** AUTOIMMUNE BULLOUS DERMATOSES, COMORBIDITIES.

Autoimmune bullous dermatoses are a heterogeneous group of rare dermatological diseases, characterized by vesicular bullous lesions in the skin or mucous membranes, caused by the formation of autoantibodies directed against target antigens in the skin tissue or mucous structures (1, 2).

Depending on the target cellular component, autoimmune bullous dermatoses are divided into intraepidermal diseases, which have as main representative the vulgar pemphigus (VP) and are characterized by the formation of autoantibodies against some intercellular adhesion molecules of keratinocytes - desmogleins, respectively subepidermal, represented by the bullous pemphigoid (BP), herpetiform dermatitis (HD)and acquired bullous epidermolysis, in which the autoantibodies target components of the basement membrane, with the subsequent disorganization of the dermal-epidermal junction (2).

Autoimmune bullous dermatoses (ABDs) are associated with a variety of systemic comorbidities, determined either by skin pathology or by the effects of systemic corticosteroid treatment. The most important comorbidities encountered in autoimmune bullous dermatoses belong to the cardiovascular sphere (high blood pressure, rhythm disorders, heart failure), neurological (stroke), psychiatric (sleep disorders, symptoms of anxiety or depression), metabolic (abdominal obesity, diabetes mellitus, metabolic syndrome, dyslipidemia), ocular (dry eye syndrome, corneal opacity) or infectious (bacterial, viral, fungal infections) (1, 3).

A special correlation between certain types of comorbidities and different autoimmune bullous dermatoses was observed. Some comorbidities, such as neoplastic pathology (solid metastases, malignant lymphoma), diabetes mellitus or osteoporosis, are more often found in patients with vulgar pemphigus, while cardiovascular, renal, pulmonary (sleep apnea syndrome, chronic obstructive pulmonary disease) or neuropsychiatric diseases (epilepsy, dementia, Parkinson's disease, cerebrovascular diseases, multiple sclerosis, schizophrenia) are predominantly present within the bullous pemphigoid. Also, pemphigus vulgaris is more commonly associated with other diseases of autoimmune etiology (autoimmune thyroiditis, type 1 diabetes, rheumatoid arthritis, inflammatory bowel disease) compared to the general population (2, 4).

Autoimmune diseases have a higher incidence in patients with a personal pathological history of autoimmunity. Thus, once an autoimmune pathology has developed, the risk of developing a new disease with similar pathogenesis is 25% of cases, usually at a certain time frame (5).

Vulgar pemphigus may occur in patients known with thymoma, myasthenia gravis, or systemic lupus erythematosus. It has also been reported to be associated with HIV disease, and immunosuppressive treatment used in bullous pathology can cause progression of viral disease. A small number of studies show associations of pemphigus vulgaris with other dermatological diseases such as psoriasis vulgaris, lichen planus, alopecia areata, vitiligo or Darier's disease (5). Due to the damage of the mucous barrier in pemphigus vulgaris, an increase in the incidence of infections is observed in this category of patients, namely those of viral (herpes simplex), bacterial (impetigo) or fungal (oral candidiasis), respectively urinary tract and lung infections (4).

Less common variants of pemphigus vulgaris may be associated with other autoimmune or neoplastic diseases. *Pemphigus vegetans* is correlated with pulmonary, gastric, colonic carcinomas or lymphosarcoma, the herpetiform form may develop in association with prostate or lung cancer, while foliaceous and erythematous subtypes can be identified in patients with thymomas, myasthenia gravis or rarely, with pre-existing dermatological pathologies (vulgar psoriasis, mycosis fungoides, oral lichen planus) (5).

Paraneoplastic pemphigus is an autoimmune syndrome, predominantly observed in association with other benign or malignant neoplastic disorders. The most common neoplasms present in a patient with paraneoplastic pemphigus are hematologic (84% of cases) such as non-Hodgkin's lymphoma, chronic lymphocytic leukemia (CLL), Castleman's disease, or Waldenstrom's macroglobulinemia. Other tumors associated with this autoimmune bullous dermatosis are pancreatic, uterine, renal, or hepatocellular cancer. There are a

number of neoplasms without direct association with paraneoplastic pemphigus, such as breast, intestinal, lung adenocarcinoma or basal cell and squamous cell skin carcinomas (5).

Bullous pemphigoid is predominantly found in the geriatric population over the age of 60, on average 80 years, which supports its possible association with oncological diseases (3, 4). A correlation has also been described between bullous pemphigoid and other types of systemic autoimmune diseases, such as SLE, vitiligo, dermatomyositis, polymyositis, Graves' disease, rheumatoid arthritis, Hashimoto's thyroiditis, HIV infection, autoimmune neutropenia or thrombocytopenia, or glomerulonephritis with immune complexes. Other pathologies associated with bullous pemphigoid include pernicious anemia, ulcerative colitis, polymyalgia rheumatica, primitive biliary cirrhosis, Kaposi's sarcoma, nephritis and glomerulonephritis, morphea, and acquired hemophilia (5). In addition, cross-reactions between common sequences of target antigen isoforms in the skin (BPAG1) and the nervous system play a key role in the association of bullous pemphigoid with neurological diseases such as schizophrenia, Parkinson's disease, multiple sclerosis, or epilepsy (4).

Among representatives of subepidermal autoimmune bullous dermatoses, herpetiform dermatitis is associated with the presence of diabetes mellitus and thyroid pathology (hypothyroidism) in 10% - 49% of cases, but also mild or subclinical Crohn's disease (3.3-18%). In patients with untreated underlying bullous dermatosis, an increase in the frequency of non-Hodgkin's lymphomas and T-cell lymphomas involving the gastrointestinal tract is observed. In addition, the neurotoxic effect of gluten predisposes to the association of herpetiform dermatitis with neuropsychiatric disorders (epilepsy, dementia, ataxia) in 25% of cases with gluten enteropathy (4).

As regards cardiovascular comorbidities, the most common risk factors in autoimmune bullous dermatoses are high blood pressure, dyslipidemia characterized by hypertriglyceridemia and hypercholesterolemia, and diabetes mellitus, respectively. Abdominal obesity, ischemic heart disease, peripheral vascular disease, cerebrovascular disease, or heart rhythm disorders have a significantly lower association. On the one hand, the link between cardiovascular and dermatological pathology is supported by chronic systemic inflammation that underlies the autoimmune response in bullous dermatoses. On the other hand, systemic and topical corticosteroids used in the treatment of these skin pathologies have multiple adverse effects, including increased risk of hypertension and diabetes mellitus among patients with autoimmune bullous dermatoses (1, 4).

Eye disorders in patients with autoimmune bullous dermatoses are frequently underdiagnosed and underestimated, but are found in up to 77.3% of cases. The most important ophthalmological comorbidity within bullous dermatological pathologies is represented by dry eye syndrome. Other less common complaints include local eye irritation, pain, burning sensation, decreased visual acuity, conjunctival scars, and simblefaron. In untreated bullous dermatoses, important eye complications such as conjunctival inflammation, trichiasis to complete corneal opacity and perforation can occur, which substantially compromises the quality of life of patients (3).

Long-term use of systemic corticosteroids to control disease activity, decreased

mobility in the elderly, and persistence of chronic inflammatory status are risk factors contributing to osteoporosis (40.4%) and bone disease in patients with autoimmune bullous dermatoses. Mild forms of pemphigus vulgaris are correlated with osteopenia, while moderately severe disease is associated with osteoporosis (6).

MATERIALS AND METHODS

We performed a retrospective study on the patients with autoimmune bullous dermatoses in evidence of the clinical hospitals from Northeastern Romania, mostly from "Sf. Spiridon" County Clinical Emergency Hospital of Iasi. Two hundred and twenty-five patients with autoimmune bullous diseases residing in the cities of the northeast region of Romania were enrolled in the present retrospective study between January 2014 and December 2019. Data were collected from the electronic database of the University Hospitals. In this analysis, inclusion criteria were a diagnosis of pemphigus vulgaris, bullous pemphigoid, or dermatitis herpetiformis confirmed by histopathology or/and direct immunofluorescence (DIF). Data on risk factors and comorbidities were analyzed. The study protocol was approved by the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy in Iasi.

Statistical analysis was performed using the *SPSS version 29.0* software package (SPSS Inc., Chicago, IL, USA).

RESULTS

Most of the patients (81.3%) are non-smokers (tab. I); however, the percentages of smokers are statistically significantly different between the 4 diagnostic categories ($p = 0.002$). The highest percentage of smokers is found among patients with HD (35.1%); in contrast, only 20.5% of those with pemphigus smoke, and only isolated cases of those with bullous pemphigoid (3.7%). Epidemiological evidence suggests that smoking cigarettes may be beneficial in pemphigus, but no systematic evaluation exists to corroborate this assumption (7).

Similarly, the majority of patients (82.7%) do not consume alcohol (tab. II); and in this case the percentages of alcohol drinkers are statistically significantly different between the 4 diagnostic categories ($p = 0.043$). The highest percentage of alcohol users is also found among patients with HD (29.7%); this percentage decreases significantly among those with pemphigus (18.2%), and reaches isolated cases of those with bullous pemphigoid (7.4%).

TABLE I.

Smoking

		Pemphigus		Bullous pemphigoid		Mucous membrane pemphigoid		Herpetiformis Dermatitis		Total	
		N	%	N	%	N	%	N	%	N	%
		Pearson's Chi-square = 15.310; p = 0.002**									
	0	105	79.5%	52	96.3%	2	100.0%	24	64.9%	183	81.3%
	1	27	20.5%	2	3.7%			13	35.1%	42	18.7%
Total		132	100.0%	54	100.0%	2	100.0%	37	100.0%	225	100.0%

TABLE II.

Alcohol consumption

		Pemphigus		Bullous pemphigoid		Mucous membrane pemphigoid		Herpetiformis Dermatitis		Total	
		N	%	N	%	N	%	N	%	N	%
		Pearson's Chi-square = 8.167; p = 0.043*									
	0	108	81.8%	50	92.6%	2	100.0%	26	70.3%	186	82.7%
	1	24	18.2%	4	7.4%			11	29.7%	39	17.3%
Total		132	100.0%	54	100.0%	2	100.0%	37	100.0%	225	100.0%

62.2% of patients have various associated diseases (tab. III), the percentages being statistically significantly different between the 3 investigated diagnosis categories (p = 0.037). The highest percentage of patients with associated diseases is found among those with bullous pemphigoid (77.8%); the percentage decreases in patients with DH (64.9%) and in those with pemphigus (55.3%), reaching 50% of those with mucous membrane pemphigoid.

Comparative analysis by type of associated diseases, however, reveals statistically significant differences only in the case of diagnoses of Essential Hypertension (EH) and diabetes mellitus (DM). Thus, the incidence of EH is significantly higher in patients with bullous pemphigoid (50.0%) compared to the other diagnostic categories, for which it is around 25% - while none of the patients with pemphigoid mucous membranes have EH. Similarly, the incidence of DM is also significantly higher in patients with bullous pemphigoid (29.6%) compared to the other diagnostic categories: HD (18.9%) and pemphigus (7.6%) - while none of the patients with mucous membrane pemphigoid has DM. The other associated diagnoses usually recorded a low case, and relatively uniformly distributed between patients with pemphigus, bullous pemphigoid and HD – the two patients with scar pemphigoid generally do not have associated diseases.

TABLE III.

Associated diseases

		Pemphigus		Bullous pemphigoid		Herpetiformis Dermatitis		Total	
		N	%	N	%	N	%	N	%
	0	49	44.7%	2	22.2%	3	35.1%	54	37.8%
	1	63	55.3%	32	77.8%	24	64.9%	119	62.2%
Total		112	100.0%	34	100.0%	27	100.0%	173	100.0%

A predilect correlation between certain types of comorbidities and different autoimmune bullous dermatoses is observed. Some comorbidities, diabetes mellitus, or high blood pressure are more often found in patients with bullous pemphigoid, while

vulgar pemphigus is more commonly associated with other diseases of autoimmune etiology (vitiligo), in comparison to the general population. Diabetes mellitus occurs as an autoimmune response against BP antigens, which is transformed by the glycosylation of proteins at the dermo-epidermal junction in pemphigoid patients (8).

DISCUSSION

The incidence of autoimmune bullous dermatoses is constantly increasing.

Smoking and alcohol consumption are not considered trigger factors in the occurrence of autoimmune bullous dermatoses, but as a percentage, most patients who drink alcohol and smoke are those diagnosed with herpetiform dermatitis. There are studies indicating that smoking may be a possible protective factor in autoimmune bullous dermatoses (9).

The most important comorbidities encountered in autoimmune bullous dermatoses belong to the cardiovascular sphere (high blood pressure, rhythm disorders, heart failure), neurological (stroke), psychiatric (sleep disorders, symptoms of anxiety or depression), metabolic (diabetes mellitus, metabolic syndrome), or are of an infectious nature (bacterial, viral, fungal infections), given in accordance with the literature.

A predilect correlation between certain types of comorbidities and different autoimmune bullous dermatoses is observed. Some comorbidities, diabetes mellitus, or high blood pressure are more often found in patients with bullous pemphigoid, while vulgar pemphigus is more commonly associated with other diseases of autoimmune etiology (vitiligo), in comparison to the general population.

Bullous pemphigoid is predominantly found in the geriatric population over the age of 60, on average 80 years, which supports its possible association with oncological diseases. In our study, the presence of neoplasms in relatively equal percentages is observed, both in patients diagnosed with bullous pemphigoid and in those with vulgar pemphigus. In addition, cross-reactions between common sequences of target antigen isoforms in the skin (BPAG1) and the nervous system play a key role in the association of bullous pemphigoid with neurological diseases such as schizophrenia, Parkinson's disease, multiple sclerosis, or epilepsy.

As regards cardiovascular comorbidities, the most common risk factors in autoimmune bullous dermatoses are high blood pressure, dyslipidemia characterized by hypertriglyceridemia and hypercholesterolemia, and diabetes mellitus, respectively. On the one hand, the link between cardiovascular and dermatological pathology is supported by chronic systemic inflammation that underlies the autoimmune response in bullous dermatoses. On the other hand, systemic and topical corticosteroids used in the treatment of these skin pathologies have multiple adverse effects, including increased risk of hypertension and diabetes mellitus among patients with autoimmune bullous dermatoses (9).

Thus, the presence of a variety of comorbidities involving all systems and organs associated with autoimmune bullous dermatosis requires an early diagnosis of bullous dermatological pathology, extensive paraclinical examinations and an exhaustive screening of possible concomitant conditions for optimal therapeutic management.

CONCLUSIONS

Evaluation of triggering factors and comorbidities before starting treatment may assist in controlling the disease more swiftly and reducing the side effects of treat-

ment in the management of ABDs. Therefore, since autoimmune bullous disorders are associated with various comorbidities and their incidence has risen in recent years, the establishment of strategies to prevent the main comorbidities in these patients is justified.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

THE PARTICIPATION OF THE SUPERIOR AND INFERIOR THYROID ARTERIES IN THE VASCULARIZATION OF THE THYROID GLAND (Abstract): **Background and aim:** This study aims to evaluate the level of vascularization within the thyroid gland by analyzing the diameters of the Romanian population's superior and inferior thyroid arteries. **Materials and methods:** Our study was performed on angiographies by computed tomography on a LightSpeed VCT64 Slice CT on 317 thyroid arteries, 168 arteries on the right side, and 149 on the left side. The measurements of the diameters of the superior and inferior thyroid arteries were compared between sides (left/right) and sexes. **Results:** The diameter of the superior thyroid artery, right and left, we're observed on a number of 176 cases, finding it to be between 1.6-4.3 mm. The right superior thyroid artery was between 1.8-4.3 mm in diameter while the left artery was between 1.6-2.8 mm in diameter. The diameter of the inferior thyroid artery, right and left, on a number of 141 cases was found to be between 1.2-4.1 mm, the right one was between 1.7-3.9 mm and the left was between 1.2-4.1 mm. **Conclusions:** The variances in the diameters of the two arteries result in fluctuation in their respective contributions to the vascular supply of the thyroid gland. **Keywords:** THYROID ARTERIES, SUPERIOR THYROID ARTERY, INFERIOR THYROID ARTERY, MORPHOMETRY.

INTRODUCTION

The thyroid gland is most commonly vascularized by two thyroid arteries: the superior thyroid artery (STA), with its origin in the carotid system (external carotid and common carotid, either at the level of its terminal branch or from the arterial trunk below the terminal branch) and the inferior thyroid artery (ITA) with its origin in the subclavian artery (either directly from the arterial trunk or via a thyrocervical trunk). Occasionally, there may be a third thyroid artery, Neubauer's thyroid ima, present in about 10% of cases according to Paturet (1) and Moore (2). According to Jelev (3) and Roshan (4), the STAs were unique and present in all cases, and Jelev (3), finds the absence of the ITA only in the right side, without being replaced by the ima, resulting in the vascular compensation of the organ being provided by the STA, which therefore has a larger caliber. Esen (5) could not identify the right ITAs in 14 cases (2.2% of cases) and left ITAs in

45 cases (7% of cases), with both ITAs absent in six cases (0.9% of cases). According to Lippert (6), the inferior thyroid artery may be missing in 3% of cases, being supplanted by the superior thyroid.

The research was conducted to identify variances in the arterial vascularization of the thyroid gland and to emphasize the differences in arterial patterns between the left and right sides, as well as between the superior and inferior.

MATERIALS AND METHODS

The angiographies conducted via computed tomography (CTA) were reviewed retrospectively. The study focused on the Romanian Caucasian population.

The study has the accord of the local Ethics Commission (34490 / 08.08.2019) within the institution of "Sf. Apostol Andrei" Clinical County Emergency Hospital from Constanța and respects the principles of the General Regulation on Personal Data Protection (EU) 679/2016. The research was conducted following the guidelines outlined in the Helsinki Declaration and adhering to all applicable national regulations concerning patient studies. Additionally, informed consent was obtained from all participants involved in the study.

Our study was performed on a number of 317 thyroid arteries, 168 arteries on the right side, and 149 on the left side. In male subjects, there were 158 thyroid arteries (49.84% of cases), 82 cases on the right side (51.90% of cases), and 76 on the left side (40.10% of cases). In female subjects, there were 159 thyroid arteries (55.43% of cases), 86 cases on the right side (54.09% of cases), and 73 arteries on the left side (45.91% of cases).

The study involved measuring the diameters of the superior and inferior thyroid arteries, comparing them bilaterally and superior with inferior, as well as by sex. It is noted that not all anatomical landmarks were consistently observed in the cases studied, with each landmark being observed in a specific number of cases as outlined in the results. Diameters were not measured in cases with an ima thyroid artery, and the origin of the thyroid arteries was not factored into the measurements.

The inclusion criterion in the study was disease-free arteries, while patients after neck surgery and with atherosclerosis were excluded. The mean ages of the males and females were 66.5 ± 17.5 and 51.5 ± 30.5 years, respectively.

RESULTS

For the diameter of the STA, on the right and left sides, we followed 176 cases and found it to be between 1.6-4.3 mm. The right STA in 90 cases was between 1.6-3.9 mm in diameter and the left STA in 86 cases was between 1.8-4.3 mm in diameter. In 84 cases in the male gender, the diameter of the STA was between 1.8-3.3 mm, in 44 cases the diameter of the right STA was between 1.8-3.3 mm, and in 40 cases the diameter of the left STA was between 1.8-2.8 mm. In female subjects, in 92 cases, the diameter of the STA was between 1.6-4.3 mm, in 46 cases the diameter of the right STA was between 1.6-3.9 mm, and in 46 cases the diameter of the left STA was 1.8-4.3 mm.

The diameter of the right and left ITA in 141 cases was found to be between 1.2-4.1 mm. The right ITA in 78 cases was between 1.7-3.9 mm in diameter and the left ITA in 63 cases was between 1.2-4.1 mm in diameter. In 74 cases of male subjects, the ITA diameter was between 1.2-4.1 mm, in 38 cases the right ITA diameter was between 1.7-3.5 mm, and in 36 cases the left ITA diameter was between 1.2-4.1

mm. In female subjects, the ITA diameter was between 1.7-3.9 mm in 67 cases, for the right ITA it was between 1.7-3.9 mm in 40 cases and for the left ITA, it was between 1.9-3.6 mm in 27 cases.

DISCUSSION

On a total of 80 CTA, we compared right/left STA diameters, finding that in 30 cases (37.50% of cases) the right STA diameter was larger than the left STA diameter with differences ranging from 0.1-1.5 mm. In 44 cases (55.0% of cases) the left STA diameter was larger with differences ranging from 0.1-1.4 mm. In 6 cases (7.5% of cases) the diameters of the two arteries were equal.

In males, from 44 cases (55.0% of cases), the diameter of the right STA was larger in 14 cases (31.82% of cases), with differences ranging from 0.1-1.3 mm.(fig. 1). In 28 cases (63.64% of cases), the diameter of the left STA was larger, with differences ranging from 0.1-1.0 mm. In 2 cases (4.55% of cases) the diameter of the right STA was equal to that of the left STA. (fig. 2).

In females, out of 36 cases (45.0% of cases), the diameter of the right STA was larger in 16 cases (44.44% of cases), with differences ranging from 0.1-1.5 mm. Also, in 16 cases (44.44% of cases), the diameter of the left STA was larger, with differences ranging from 0.1-1.4 mm. (fig. 3). In 4 cases (11.11% of cases) the diameter of the right STA was equal to the diameter of the left STA.

For Gursharan (7) and Ozgur (8), the STA is the main source of arterial blood for the thyroid gland. According to Paturet (1), the superior thyroid artery is relatively bulky, and when the superior thyroid artery is very thin, the one on the opposite side is usually larger, supplanting it.

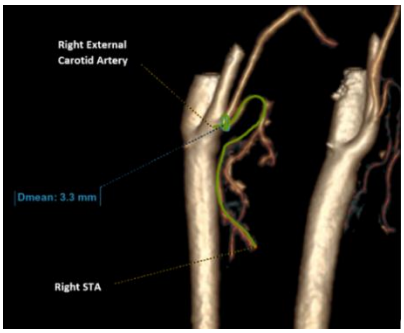

Fig. 1. The diameter of the right STA is 3.3 mm (male subject)

Fig. 2. The diameter of the right STA is 2.2 mm, equal to the diameter of the left STA; the diameter of the left ITA is 2.0 mm larger than the diameter of the right ITA (1.8 mm) by 0.2 mm (male subject)

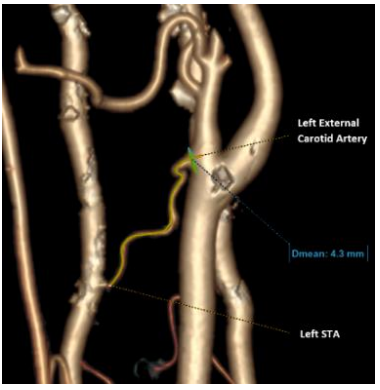

Fig. 3. The diameter of the left STA is 4.3 mm (female subject)

Different authors have identified differences in the caliber of the STA in cadavers, ranging from 1.04-6.1 mm (tab. I).

Comparing the results found by us with those reported in the literature, it appears that at the minimum measure level, it is smaller than that found by several authors (4, 10, 13, 14) with differences of 0.1-4.3 mm, larger than Ozgur (8 (right side)) and Troupis (12) with 0.3-0.74 mm and equal to the diameter found by Ozgur (8 (left side)). The maximum diameter found by us is smaller than that found by some authors (4, 7 (right and left), 10) with differences of 0.1-1.8 mm and larger than the diameter found by various authors (1, 12, 13, 14) with differences of 1.0-1.8 mm.

TABLE I.

Diameter of the superior thyroid artery in literature

Authors	Type of study	Diameter of STA (mm)
Fujimoto (1974) (9)	cadaver	3.3 (R); 2.7 (L)
Zhao (1999) (10)	cadaver	1.9
Jelev (2001) (3)	cadaver	4.4
Ozgur (2008) (8)	cadaver	1.5-6.1 (R); 1.8-5.5 (L)
Vazquez (2009) (11)	cadaver	2.6
Troupis (2014) (12)	cadaver	1.04
Sung-Yoon (2016) (13)	cadaver	4.4
Personal cases	CTA	Male subjects (1.8-3.3) R: 1.8-3.3; L: 1.8-2.8 Female subjects: (1.6-4.3) R: 1.6-3.9; L: 1.8-4.3

On a total of 91 CTA, we compared the diameters of the ITA right/left, finding that in 30 cases (32.97% of cases) the right ITA diameter was larger than the left ITA diameter with differences ranging from 0.1-1.5 mm. In 56 cases (61.54% of cases) the diameter of the left ITA was larger with differences ranging from 0.1-1.4 mm. In 5 cases (5.49% of cases) the diameters of the two arteries were equal. In male subjects, in 45 cases (49.45% of cases), the right ITA diameter was larger in 22 cases (48.89% of cases), with differences ranging from 0.1-1.3 mm. Also, in 22 cases (48.89% of cases), the left ITA diameter was larger with differences ranging from 0.1-1.0 mm (fig. 4)In only one case (2.22% of cases) was the right ITA diameter equal to the left ITA diameter. In female subjects, in 46 cases (50.55% of cases), the diameter of the right ITA was larger in 8 cases (17.39% of cases), with differences ranging from 0.1-1.5 mm (fig. 5). In 34 cases (73.91% of cases) the diameter of the left ITA was larger, with differences ranging from 0.1-1.4 mm. In 4 cases (8.70% of cases) the diameter of the right ITA was equal to that of the left ITA.

In the literature, we did not find the value of the ITA diameter, but the size of the artery was only mentioned in general, Testut (14) states that the ITA volume varies greatly, depending on the development of the thyroid gland and being the inverse of the ITA on the opposite side. Roshan (4), found that the ITA is usually the largest artery of the normal thyroid gland, ITA at the entrance to the hilum, representing the main functional blood source of the gland.

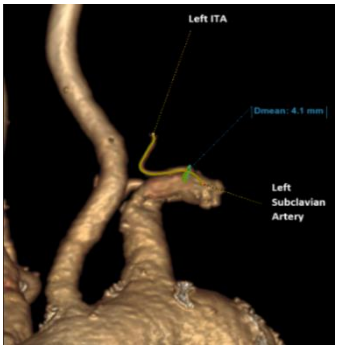

Fig. 4. The left ITA diameter is 4.1 mm (male subject)

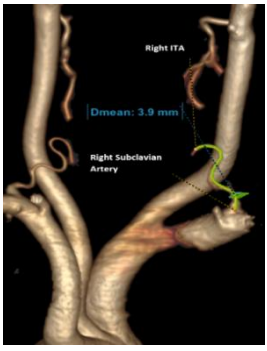

Fig. 5. The diameter of the right ITA is 3.9 mm (female subject)

We compared the diameter of the STA with the diameter of the corresponding ITA in 133 cases and found that in 66 cases (49.62% of cases) the diameter of the STA was larger by 0.1-2.0 mm (fig. 6). In 64 cases (48.12% of cases) the diameter of the ITA was larger by 0.1-2.2 mm, and in 3 cases (2.26% of cases) the diameter of the two arteries was equal. In male subjects, in 76 cases (57.14% of cases), the diameter of the STA was larger in 38 cases (50.0% of cases) with differences of 0.1-1.6 mm. In 36 cases (47.37% of cases), the diameter of the ITA was larger with differences of 0.1-2.3 mm. In 2 cases (2.63% of cases) the diameter of the two arteries was equal. In female subjects, in 57 cases (42.86% of cases), the diameter of the STA was larger in 28 cases (49.12% of cases), with differences between 0.1-2.3 mm. Also, in 28 cases (49.12% of cases) the ITA diameter was larger with differences between 0.2-1.7 mm. In only one case (1.75% of cases) the diameter of the two arteries was equal.

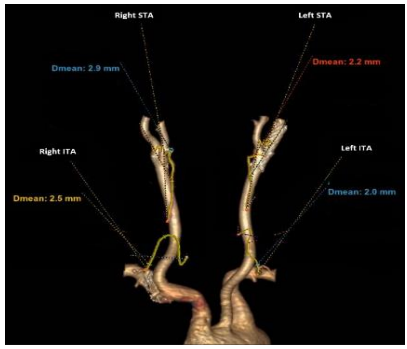

Fig. 6. The diameter of the right STA is 2.9 mm and the right ITA diameter is 2.5 mm, being 0.4 mm smaller; the diameter of the left STA is 2.2 mm, and the left ITA diameter is 2.0 mm, being 0.2 mm smaller; the diameter of the right STA is 0.5 mm larger than the diameter of the left STA; the diameter of the right ITA is 0.5 mm larger than the diameter of the left ITA (female subject)

In reviewing scientific literature, we did not come across specific citations regarding the morphometric variances in external diameter values between the superior and inferior thyroid arteries. However, we did find general information on this topic. Thus, Paturet (1) and Testut (14) noted that the volume of the inferior thyroid artery is inversely proportional to that of the superior thyroid artery on the corresponding side, as well as the inferior thyroid artery on the opposite side. As noted by Paturet (1), the superior thyroid artery typically has a significant size, with its caliber usually being slightly smaller than or equivalent to that of the inferior thyroid artery. A balancing effect is observed between the calibers of these arteries and the two superior thyroid arteries. In cases where one superior thyroid artery is thin, the one on the opposite side tends to be larger to ensure proper arterial blood supply to the gland. In a study conducted by Lippert (6), it was observed through dissections that the inferior thyroid artery typically has a larger size in comparison to the superior thyroid artery, indicating that it serves as the main artery supplying the gland. Additionally, Testut (14) notes that the volume of the inferior thyroid artery is inversely proportional to that of the superior thyroid artery on the same side.

CONCLUSIONS

There is consistent variability in percentages among different authors, often showing significant differences over the same or similar time periods. We did not come across any literature analyzing the origin of the artery based on sex, despite known differences between males and females. Few authors provide detailed percentages on the origin of thyroid arteries comparing right to left, also disparities between the two are present. It should be noted that the percentages reported may vary depending on the methodology employed.

We have not observed any instances of missing or duplicated thyroid arteries (superior or inferior) in our study. The diameters of the thyroid arteries we identified showed variations, indicating that these arteries' roles in the thyroid gland's vascular supply may vary as well. Thus, of the total cases, the right ITA was larger in diameter in 10.57% of cases and the left ITA was larger in diameter in 6.90% of cases. In the male subjects, in the right thyroid arteries, the diameter of the right STA was larger than the diameter of the right ITA in the same proportion that the diameter of the right ITA was larger than the diameter of the right STA. In female subjects, the right ITA diameter was larger than the right ITA diameter in 5.36% of cases, and the right ITA diameter was larger than the left ITA diameter in 10.52% of cases. The equality of the diameters of the two thyroid arteries, superior and inferior, was greater in females in 2.70% of cases. The minimum and maximum diameters were frequently found in only one case.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflicts of interest. This research received no external funding.

RISK FACTORS AND ANTIBODY RESPONSE ASSOCIATED WITH LONG COVID: LONGITUDINAL COHORT STUDY(Abstract): **Aims:** Although numerous studies assess risk factors for long COVID, data on humoral response are scarce and discordant. This study aimed to determine if serum antibody titers are associated with long COVID and to analyze demographic characteristics, comorbidities, treatment, and disease severity influencing its development. **Materials and methods:** We included 80 unvaccinated COVID-19 patients who contracted the disease in early 2020. Clinical data and serum samples were collected at inclusion, 33±10 days (visit 1), and 91±19 days (visit 2) post-symptom onset for symptomatic patients, and post-diagnosis for asymptomatic patients. Symptoms were tracked via questionnaires at each visit and one month after the second visit by telephone. Serum samples were analyzed to measure IgG antibodies using indirect chemiluminescent immunoassay technology. **Results:** We found 53.7% (CI95%, 42.2-65; p=0.57) of patients experienced long COVID. Female gender (OR, 1.95; CI95%, 1.12-3.41; p=0.01) and pre-existing comorbidities (OR, 1.56; CI95%, 1.02-2.38; p=0.04) were significantly associated with long COVID symptoms. Importantly, patients with long COVID had higher overall median antibody levels at both follow-up visits. While this difference was not statistically significant, it suggests a trend worth further investigation. **Conclusions:** Understanding the risk factors associated with long COVID could provide valuable insights for managing and potentially decreasing its incidence in the future. **Keywords:** LONG COVID, RISK FACTORS, GENDER, COMORBIDITIES, ANTIBODY TITER.

Long COVID, also known as chronic COVID syndrome or prolonged COVID-19 symptoms, refers to persistent health issues experienced by individuals following a COVID-19 diagnosis. These symptoms typically emerge within a few months and can significantly affect quality of life. While various definitions exist, the World Health Organization defines long COVID as the persistence or emergence of new symptoms at least three months after initial SARS-CoV-2 infection, lasting for a minimum of two months without any other clear cause (1). Estimates suggest 10–20% of

individuals may experience such symptoms (1), which encompass over 200 reported manifestations including fatigue, shortness of breath, cognitive difficulties, chest pain, and joint pain, among others (2).

Similarities to postviral syndromes observed in previous coronavirus diseases like MERS and SARS highlight the long-term impact of such infections, with symptoms such as fatigue and psychiatric impairments persisting for years (3, 4). Identifying risk factors, both pre-infection (e.g., age, sex, comorbidities) and infection-associated (e.g., disease severity, viral load), is crucial for predicting, preventing, and managing long COVID (5).

Understanding the role of antibody response dynamics is pivotal for developing effective treatments and interventions (6). However, studies on humoral responses in long COVID have yielded conflicting results, with some indicating higher antibody titers associated with persistent symptoms (7,8), while others suggesting lower titers (9).

This study aimed to investigate the association between serum antibody titers and long COVID, while analyzing demographic characteristics, comorbidities, treatment, and disease severity as potential risk factors for its development. By elucidating these factors, this research contributes to ongoing efforts in managing and potentially reducing the incidence of long COVID in the future.

MATERIALS AND METHODS

Patients and collection of serum samples and clinical data

Adult patients aged 18 years or older diagnosed with SARS-CoV-2 infection via positive reverse transcription polymerase chain reaction (PCR) tests from nasopharyngeal swabs were consecutively recruited for this study. The study population was drawn from a larger investigation conducted at the onset of the COVID-19 pandemic, focusing on the clinical performance of six commercially available assays, including the chemiluminescent immunoassay (CLIA) IgG antiS1/S2 (10). Enrollment commenced in May 2020, with baseline blood samples collected during hospitalization: 6+/-10 days post-symptom onset (PSO) for symptomatic patients, and post-day of diagnosis (PDD) defined as the first positive PCR for asymptomatic patients. Subsequent serum samples were obtained at 33+/-10 days (visit 1) and 91+/-19 days (visit 2) PSO for symptomatic patients, and PDD for asymptomatic patients. Demographic and clinical data were collected concurrently. Only patients who completed visit 2 were included in the analysis. Specimens were processed within 5 days of collection: stored at 4 °C, centrifuged, aliquoted, and frozen at −20 °C until analysis. Data on demographic characteristics (age, gender), comorbidities, and COVID-19 clinical classifications (mild, moderate, severe) were collected using a questionnaire based on WHO criteria. Persistent or new symptoms were assessed at each visit, with a follow-up telephone questionnaire (Annex 1- Post-COVID Questionnaire) conducted one month after visit 2 for symptomatic patients.

Long COVID was defined as the persistence or emergence of signs, symptoms, or conditions beyond three months post-acute COVID-19 infection, lasting over one month without an apparent cause. Patients reporting at least one persistent symptom fitting these criteria were classified as having long COVID.

Ethical approval was obtained from the hospital's local ethics committee, and all participants provided written informed consent for serial blood sampling.

Assays. Nasopharyngeal swabs were analyzed for SARS-CoV-2 RNA using the Allplex™ SARS-CoV-2 Assay and the CFX96 Real-Time PCR Detection System. Serum samples were tested for IgG antibodies against SARS-CoV-2 S1/S2 using the LIAISON® SARS-CoV-2 S1/S2 IgG assay on the Liaison XL platform, with results reported in arbitrary units (AU/mL). Samples with a value of ≥15 AU/ml were interpreted as positive, 12.0 ≤ AU/mL < 15.0 equivocal, and < 12.0 AU/mL as negative.

Statistical analysis employed IBM® SPSS® Statistics version 26.0. Descriptive statistics included median values with interquartile range (IQR). Results are presented as total values and percentages with 95% confidence intervals. Mann-Whitney U test compared categorical variables, and Fisher's exact test analyzed categorical variables between patients with and without long COVID symptoms. Odds ratios (ORs) with 95% confidence intervals were calculated. A p value <0.05 indicated significance.

RESULTS

A total of 93 patients were initially recruited in the study, but by the end of the study two patients died and 11 were lost to follow-up. Among them, 44 were males (55%, p=0.43), median age 49.5 (IQR 38.2-57). Five patients (6.25%, p=0) had been asymptomatic, 32 (40%, p=0.09) had a mild form of the disease, 25 (31.25%, p=0.001) had moderate disease and 18 of them (22.5%, p=0) had severe disease. Comorbidities were recorded in 45 patients (56.25%, p=0.31) as illustrated in Table 1, with arterial hypertension being the most common one.

Forty-three patients (53.75%, p=0.57) had long COVID symptoms; refer to Table 2 for specific symptoms.

Other Long Covid symptoms: diaphoresis, arterial hypertension, alopecia, headache, visual acuity disturbances (hypermetropia, myopia), ulnar neuropathy, sneeze, and rash

TABLE I.

Associated comorbidities

Comorbidities	N (%)
Arterial hypertension	26 (32.5)
Diabetes mellitus	12 (15)

DISCUSSION

Long COVID poses challenges for healthcare systems, demanding a multidisciplinary approach (5). Ongoing research has identified risk factors like older age, female gender, and pre-existing conditions (11), but much remains unknown about why symptoms persist variably among individuals. Literature on chronic COVID reflects diverse symptom persistence due to

sample characteristics, study methodologies, and the fact that long COVID exhibits significant heterogeneity.

Long COVID's mechanisms may involve sustained tissue damage and inflammation (5). Survivors often experience multi-organ complications, such as pulmonary (12), neurological (13), cardiac (14), and others (15). Pathological inflammation, including prolonged virus shedding (16), immune dysregulation involving T and B cells (17, 18), and disrupted gut microbiome (19), likely contributes to persistent symptoms.

Ideal for long COVID research is a diverse cohort of individuals recovering from SARS-CoV-2 infection, ranging from mild to severe cases, with persistent symptoms post-acute phase. Longitudinal tracking is crucial to monitor symptom evolution across organ systems. Including hospitalized and non-hospitalized patients, diverse demographics, and comorbidities would capture comprehensive long COVID manifestations and risk factors. Our cohort includes 80 patients recovering from various SARS-CoV-2 clinical forms, from asymptomatic to severe, with ongoing symptoms three to four months post-acute phase. It features balanced gender representation and diverse comorbidity profiles.

Regarding long COVID symptoms in survivors, fatigue was prominently reported in our patient cohort, consistent with findings from other studies (20, 21). Approximately half of our patients experienced fatigue three months post-SARS-CoV-2 infection. Dyspnea, cognitive impairment, and arthralgia affected nearly a quarter of our cohort. Studies with higher dyspnea prevalence, up to 61%, likely included more severe cases and ICU admissions (20, 22), unlike our cohort where severe cases were 22.5% and no ICU admissions occurred. Other symptoms like anosmia, anxiety, and cough were less frequent (23, 24).

Numerous studies are focused on demonstrating that specific epidemiological and clinical risk factors are associated with an increased likelihood of developing long COVID symptoms.

Our study identified a significant association between female gender and increased risk of long COVID symptoms compared to males (OR, 1.95; CI95%, 1.12 to 3.41; p =0.014). This finding is consistent across several individual studies (8, 25-27,) and meta-analyses (11, 28). Studies such as Bai *et al.* (25) reported females having 2.7 times higher odds of long COVID symptoms (CI95%, 1.68 to 4.62), while Asadi-Pooya *et al.* (26), Chudzik *et al.* (27), and Peghin *et al.* (8) reported odds ratios of 1.26 (CI 95%, 1.12 to 1.43), 1.44 (CI95%, 1.20 to 1.70), and 1.55 (CI95%, 1.05 to 2.27), respectively. Meta-analyses by Kin Israel Notarte *et al.* (11) and Maglietta *et al.* (28) also showed significant associations with approximately 50% higher risk for females. The reasons for this gender disparity in long COVID risk are not fully understood, but potential factors include the influence of female hormones on sustaining post-recovery inflammation (29) and higher acute phase mortality rates among males during COVID-19 (30).

The influence of age on long COVID is still debatable, despite the well-established understanding that older age is a significant risk factor for adverse outcomes during COVID-19 hospitalization (31). In our study as well as in the study conducted by Peghin *et al.* (8), who compared young adults under 40 with those older than 40, no association between age and long-COVID was observed. Furthermore, no such association was found in the meta-analysis conducted by Kin Israel Notarte *et*

al. (11) (OR, 0.86; 95%CI 0.73 to 1.03, p = 0.17) who compared individuals under the age of 60 with those aged 60 and above. One possible explanation for this discrepancy includes the inadequate control of confounding factors observed in older individuals, such as a higher prevalence of medical comorbidities or longer hospitalization stays, which may also contribute to developing long COVID (11).

The severity of acute COVID-19 illness does not appear to predict the development of long COVID. Research indicates that long COVID can impact individuals with mild-to-moderate cases, including younger adults treated as outpatients (5). Consistent with other studies (32, 33), we found no association between initial disease severity and long COVID. In contrast, Tsampasian *et al.*'s meta-analysis highlighted severe illness as a significant risk factor (34). ICU survivors may experience post-intensive care syndrome, overlapping with long COVID symptoms (35). Our study, with few severe cases and none in the ICU, underscores the need for further exploration into these complexities.

Comorbidities are recognized as potential risk factors for long COVID. Studies have linked conditions like diabetes (36), obesity (34, 37), cardiovascular disease (36, 37), and respiratory disorders (38) to a higher likelihood of persistent symptoms post-COVID-19 recovery. Consistent with this research, our study found that having comorbidities significantly increased the risk of long COVID (OR, 1.56; CI95% 1.02 to 2.38; p 0.04). Dyslipidemia showed a particularly strong association (OR, 6.88; CI 95% 0.90 to 52.51; p 0.03), though our cohort size limited statistical significance for other conditions. Pretorius *et al.* also noted elevated cholesterol and conditions like hypertension and type 2 diabetes as significant in long COVID (36). Lipid metabolism disorders and obesity represented age-independent risk factors for long COVID syndrome indicating that metabolic changes play a significant role in determining the severity of the disease throughout all stages of COVID-19 in another study conducted by Loosen *et al.* (37).

Similar to other research findings, we found no association between the treatment administered during the acute phase of SARS-CoV-2 infection and long COVID (39).

The long COVID group revealed overall higher median titers of IgG anti-S1/S2 antibody at visit 2 and visit 3, compared to baseline where no disparities were noticed, with no statistically significant differences observed at any time point. Also, when comparing median antibody antiS1/S2 concentration according to the disease severity and time PSO between the two groups, no statistically significant differences were observed. Similar to our results, no association was observed between increased specific immunity evaluated by qualitative IgG antibodies directed against S1 protein using in vitro SARS-CoV-2 ELISA assay and long-term complications in a study conducted by Rank *et al.* (7). Interestingly, Klein *et al.*, found that the long COVID state positively predicted the anti-spike humoral response with significant differences among the various epitopes (40). Potential explanations suggest that long-term complications following COVID-19 may be due to virus-specific pathophysiological changes, immunological dysregulation, and inflammatory damage initiated by the acute infection. However, the involvement of the SARS-CoV-2 specific humoral immune response in post-COVID syndrome remains unclear, given the incomplete and sometimes conflicting data, potentially arising from differences in

methodological approaches.

Our study's strength lies in its focus on unvaccinated patients recruited early in the pandemic, ensuring antibody responses were not influenced by prior COVID-19 infection or vaccination. Further studies are needed to determine the usefulness of measurement of antibody titers for prognosis of long COVID symptoms.This research surpasses the examination of recognized risk factors and extends its focus to explore the complex interaction between antibody titers and the emergence of long COVID over different timeframes. A limitation of this study is its small sample size, although it included participants with varying disease severities from asymptomatic to severe cases. Due to the limited number of patients, not all potential long COVID symptoms may have been captured. While we followed up with patients for at least three months, longer-term observation is needed to understand symptom persistence fully. Another limitation is the use of a single serological method, LIAISON® SARS-CoV-2 S1/S2 IgG (DiaSorin), chosen based on its superior sensitivity and specificity compared to other serological assays, as supported by recent literature (10, 41).

CONCLUSIONS

The study identified female gender and pre-existing medical conditions as potential risk factors for long COVID symptoms. Factors such as age, disease severity during acute COVID-19, immunomodulatory treatment, and antibody levels were not associated with long COVID symptoms. Nonetheless, the current literature does not conclusively identify the risk factors associated with long COVID symptoms. Through the inclusion of analyses conducted at various intervals, the study provides insight into the possible role of antibody dynamics in the development of this condition.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no external funding regarding this scientific research.

ACKNOWLEDGMENTS

Extend our appreciation to Roxana Vasilescu from the Medlife laboratory for her work in analyzing the presence of antibodies in serum samples using the high-throughput automated serological assay, LIAISON® SARS-CoV-2 S1/S2 IgG (DiaSorin).

THE CLINICAL FACTORS OF EVOLUTION AND PROGNOSIS IN CUTANEOUS SEPSIS: DERMATOLOGIST'S PERSPECTIVE IN SEVEN BASIC STEPS (Abstract): Disturbances of the skin microbiome characterize a variety of infectious and inflammatory dermatoses with important impact on the quality of life. Most of these have presents a skin manifestation one or more lesions with loss of tissue, which are infected with microorganism. Increased mortality because of sepsis and increased incidence of organ dysfunction are a global health problem. Pathophysiological mechanism from skin infection to sepsis evolves rapidly, by triggering a complex cascade involving inflammatory and coagulation processes. **Materials and methods:** Clinical factors of evolution and prognosis, together with skin changes, are essential elements in the management of cutaneous sepsis. This retrospective observational study aims to assess clinical risk factors in cutaneous sepsis and their involvement in the evolution and prognosis of this disease. A total of 441 medical documents of patients with skin lesions with loss of tissue, in various stages of evolution, admitted to dermatology over a period of 3 years were analyzed. Out of the 441 infectious dermatoses, 363 had a favorable evolution, without septic complications and 78 presented sepsis. The most frequent skin infections were: venous ulcers, microbial eczema, cellulitis, superinfected bullous dermatoses (pemphigus, bullous pemphigoid, dermatitis herpetiformis), erysipelas, erythroderma. **Results**: Skin semiology was correlated with risk factors such as smoking, obesity, using invasive devices and with comorbidities - cardiovascular, metabolic and neuropsychiatric. This way it was described the correlation between skin-sepsis in seven basic steps. **Conclusions:** The study illustrates the importance of skin manifestations, which although they are initially not important, should not be neglected, as they can become bacterially infected and progress to severe infections, even sepsis, with a fatal prognosis. At the same time, this study encourages further research for a prompt and appropriate approach of cutaneous sepsis. **Keywords**: CUTANEOUS SEPSIS, RISK FACTORS, SKIN INFECTIONS.

INTRODUCTION

Over the last 30 years, sepsis has been the focus of research and clinical debate, with multiple dynamic challenges, repre-

senting one of the major life-threatening health problems in the absence of urgent and appropriate intervention.

Throughout this time, the concept of *sepsis* was modified as a result of advances in understanding the mechanisms that produce it. These highlights that the clinical manifestations of sepsis are attributed to the infectious agent, the immune response it generates, changes in coagulation parameters, immunosuppression and organ dysfunction (1).

Currently, according to the third international consensus, sepsis is known as *sepsis-3* and is a life-threatening organ dysfunction, recognizing the severity and lethality triggered by a pathogen that invades the body (2, 3). Organ dysfunction is defined as an acute change in the total Sequential Organ Failure Assessment (SOFA) score of at least 2 points as a result of infection (4).

The current available data on the incidence of cutaneous-onset sepsis is limited. Some reports indicate that cutaneous and soft tissue infections cause 14 million visits per year in the US and approximately 900,000 hospitalizations annually. In Europe the situation is similar, with 1,250 episodes of acute skin infections reported in emergency department, of which 3.3% had sepsis (5, 6, 7).

Skin and soft tissue infections (SSTIs) are prevalent in the elderly, with a varied clinical spectrum from mild infections to septic complications. The prognosis becomes severe depending on comorbidities such as heart failure, diabetes mellitus, anemia. SSTIs represents a management challenge, especially in emergency hospitals and chronic care institutions, where their prevalence is significant - 10.9% and 17% (8).

Clinical risk factors which are influencing the prognosis are: age - patients over 65 years of age are vulnerable, due to a inefficient immune system, to act appropriately on the bacterial invasion; comorbidities - cardiac, oncological, renal or any other medical condition that compromises immunity and decreases the body's ability to defend itself (diabetes, AIDS, transplant, immunosuppressive drugs, hypoalbuminemia); invasive devices: peripheral or central venous catheters, urinary catheters, mechanical ventilation; antibiotic resistance may favor the occurrence of sepsis (9).

MATERIALS AND METHODS

This retrospective observational study included 441 patients with acute bacterial skin infections admitted to the Dermatology Clinic of “Sf. Spiridon” County Clinical Emergency Hospital Iasi, between January 2020 and December 2022. The study was conducted after obtaining the approval of the Institutional Ethics Committee. The main objective is to illustrate the importance of skin manifestations in correlation with risk factors, all of there influencing the evolution and prognosis of the disease.

363 had not complicated skin infections and 78 had sepsis. The risk factors followed were: age, gender, smoking, obesity, thrombotic history, usage of medical devices (probes, catheters). Inclusion criteria: patients over 18 years of age, local and/or systemic clinical signs of infection; skin manifestations with loss of tissue (ulcerations, erosions, fissures, excoriations) associated with inflammatory phenomena - swelling, erythema, pain; bacteriological examination of the skin lesion with antibiogram on admission to the dermatology department. Exclusion criteria: patients

under 18 years of age, with SARS-Cov2 infection, patients with sepsis other than skin sepsis, severe alteration of mental status and patients with negative bacteriological examination.

Sepsis was defined based on SIRS at infection (minimum 2 criteria from: temperature > 38°C or < 36°C, tachycardia, tachypnea, leukocytosis/leukopenia) and the confirmation of bacterial agents in cultured samples from the skin lesions. The bacterial agent was identified by bacteriological examination collected (on admission to the clinic) on single-use tube swab with transport medium (Amies). The collected sample was transported within the first 4 hours to the hospital microbiology laboratory, where culture and antibiotic susceptibility testing was performed.

Statistical analysis was performed using the *SPSS version 29.0* software package (SPSS Inc., Chicago, IL, USA). Categorical variables were presented as frequencies and percentages, and continuous variables as mean ± standard deviation. Categorical variables were compared between groups using the Pearson Chi-squared test.

RESULTS

Demographic characteristics

In our study, the average age of the patients with sepsis is 61.33 ± 15.022 years. There are no statistically significant differences in terms of gender distribution (52.6% are male and 47.4% are female) and in terms of distribution by environment (rural patients predominate, but the percentages are close - 53.8% rural and 46.2% urban).

TABLE I.

Demographic characteristics

	Total		Acute Skin lesions with Sepsis		Acute Skin lesions without Sepsis	
	N	%	N	%	N	%
Sex						
male	248	56.2%	41	52.6%	207	57.0%
female	193	43.8%	37	47.4%	156	43.0%
Environment						
urban	188	42.6%	36	46.2%	152	41.9%
rural	253	57.4%	42	53.8%	211	58.1%
Total	441	100%	78	100%	363	100%

TABLE II.

Mean age of patients with acute skin infections with sepsis *versus* without sepsis.

Patients of Study	N	Mean	St. dev.	St. error	Min	Max	Median
Acute skin infections with sepsis	78	61.33	15.022	1.701	18	88	62.0
Acute skin infections without sepsis	363	65.23	14.056	0.738	18	92	65.0

Sepsis present/absent: Mann-Whitney U = 12122.000; p = 0.046*.

Lifestyle

Among the risk factors (table 3, fig.1), smoking is notable in the majority of patients included in the study, with no increased risk of developing sepsis in smokers with acute infections. Chronic staphylococcal carrier status does not predispose to an additional risk for sepsis, as there are

numerous species of the skin microbiome that are harmless as long as the skin barrier is not disrupted. In contrast, acute infections in chronic carriers of invasive medical devices, such as urinary catheters, associate a 9.757-fold increased septic risk. The same is for patients with a history of thromboembolic disease, where the risk of sepsis is 2.165 times higher, as found in 24.4% of patients with sepsis, compared with 12.9% of acute skin infections.

10.3% of patients with sepsis had prolonged immobilization and only 5,5 % of patients without sepsis, a difference that is not statistically significant. 24.4% of patients with sepsis had PTE or a history of thrombosis compared to only 12,9% of the group without sepsis, a difference that is statistically significant and is associated with a 2.165-fold increased risk in patients with PTE or a history of thrombosis of developing sepsis.

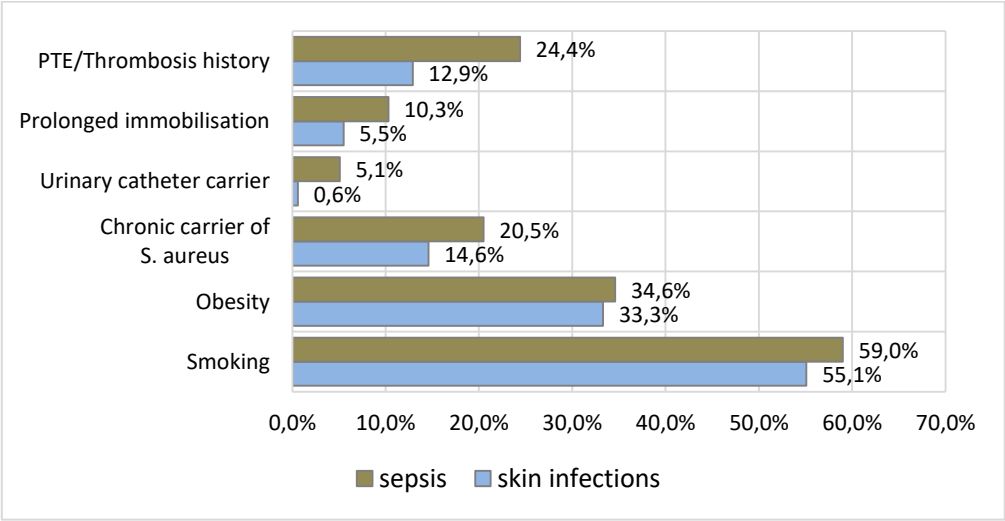

Fig. 1. Risk factors for skin sepsis *versus* acute skin infections

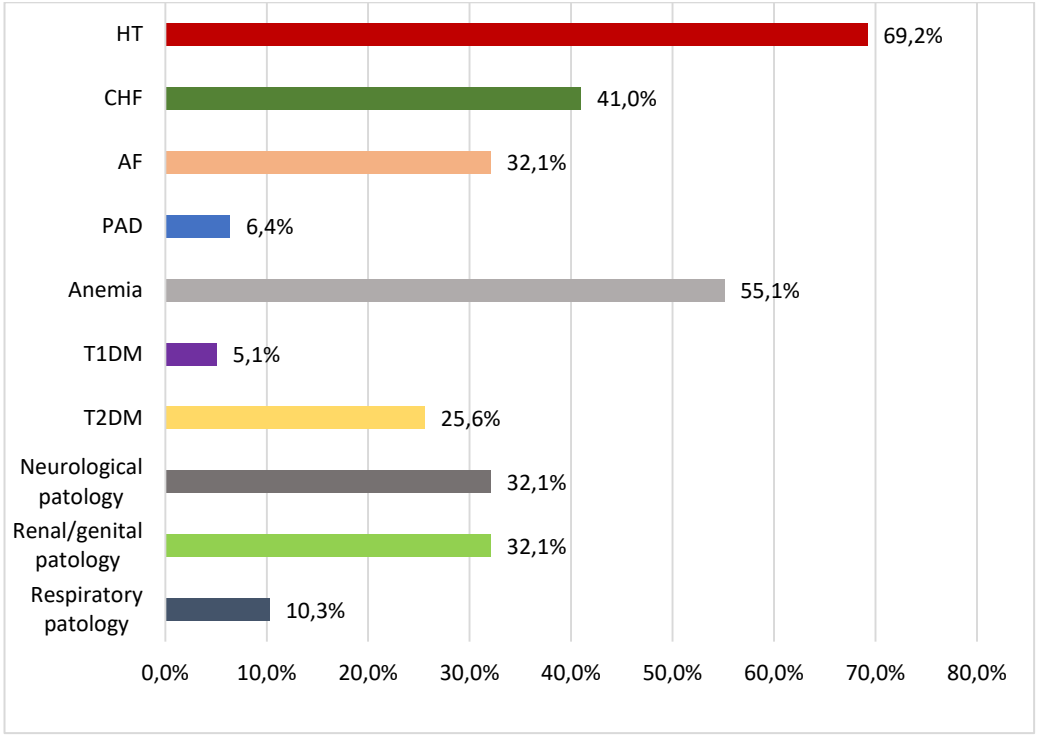

Fig. 2. Comorbidities of patients with sepsis.

Regarding the associated pathologies of patients with sepsis (fig. 2), it was found that cardiovascular diseases: hypertension (HT), chronic heart failure (CHF), atrial

fibrillation (AF), extremity peripheral arterial disease (PAD), have a significant percent. Essential hypertension occurs in 69.2% of patients, atrial fibrillation in 32.1% and heart failure in 41%. Type 1 and type 2 diabetes mellitus are common among the studied population: 5.1% of patients with sepsis have type 1 diabetes mellitus compared to 25.6% of patients with type 2 diabetes mellitus. Microcytic hypochromic anemia was also present for 55.1% of all cases. Extremity peripheral arterial disease was found in 6.4% while the proportion of neuro-psychiatric disorders (such as stroke or depressive disorders and their consequences) was of 32.1%.

The polymorphous spectrum of the cutaneous and systemic manifestations in patients with sepsis (Fig. 3) illustrates in 89.7% of cases ulcerations, erosions, fissures or excoriations. Pain was discovered in 96.2%, tumefaction in 92.3% and edema was observed in 80.8% of septic cases. The presence of bullae or vesicles is not systematically associated with sepsis, as only 21.8% of patients have this symptomatology. Pruritus was observed in 29.5% of cases.

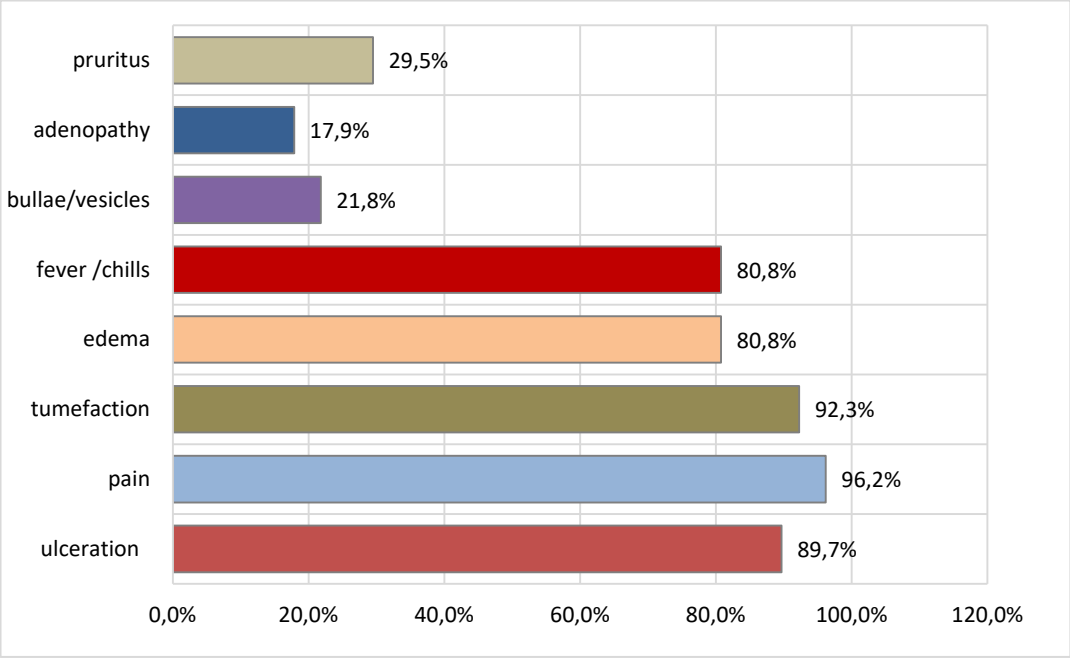

Fig. 3. Local and systemic clinical manifestations.

Another element investigated in patients with sepsis was the pathogen agent. Among the bacteria identified by culture from the cutaneous lesions (fig. 4), the data analysis shows that in 34.6% the culture is positive for *P. aeruginosa*; in 37.2% cases the culture reveals *S. aureus*, in 17.9% - *E. coli* and in 32.1% shows other bacterial species such as *P. Mirabilis*, *Serratia marcescens*, *Citrobacter freundi*, *Providencia stuartii*, *Stenotrophomonas maltophilia*, *Morganella morganii and Enterobacter*.

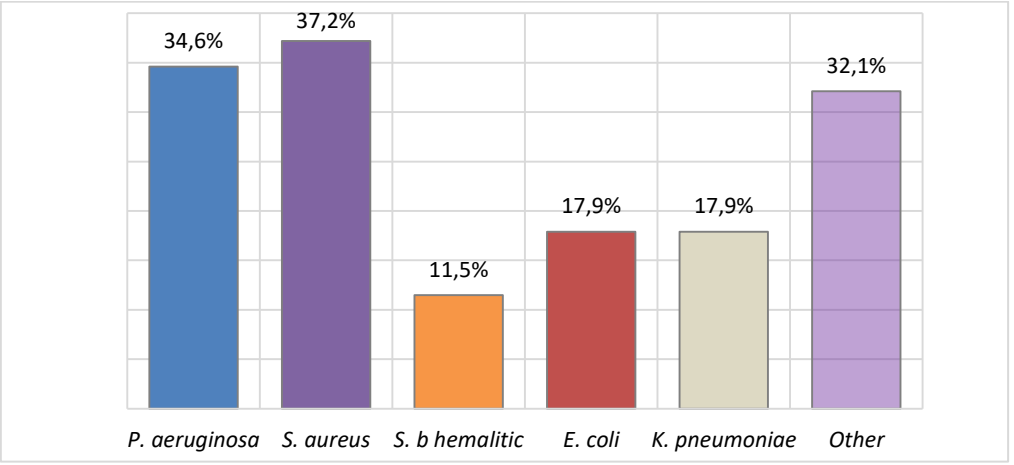

Fig. 4. Distribution of bacterial etiological agents.

DISCUSSION

Although there is lot of documented information on acute infectious dermatoses, the medical literature is poor in data related to the incidence of cutaneous-onset sepsis. By analyzing data from 441 patients with skin infections - some with septic complications - the skin-sepsis correlation was established, based on clinical risk factors grouped into seven essential steps.

Analysis of demographic characteristics

Age is a key parameter in the sepsis evolution, but recent research shows that the severity of comorbidities and organ dysfunction are closely correlated with severe prognosis (7, 10). Sepsis affects all age groups, but its incidence and mortality increase considerably with age. The complex interaction of environmental, genetic and lifestyle factors contributes to the development of chronic diseases and geriatric syndromes that decrease the length and quality of life. An emerging risk factor for age-related diseases is the microbiome. Elderly people are vulnerable to developing sepsis due to comorbidities, compromised immune function, sarcopenia, diminished physiological reserves, malnutrition and polymedication. Immunosenescence and inflammation are key factors that increase susceptibility to sepsis. Immunosenescence involves a gradual decrease in the immune system, especially T lymphocyte function (11).

There are numerous studies showing that sepsis is more prevalent among men than women. The differences between men and women in sepsis prevalence is explained on the basis of physiological characteristics, men's greater exposure to physical activity, but also biological aspects, concerning hormonal peculiarities and the immune system. Estrogens induce effective cellular and humoral mediated immune responses, while androgens have suppressive effects (12).

People from rural areas are known to have limited and delayed access to health services, such as primary and secondary health care. Limited access on low developed areas contributes to delays in the

management of sepsis and comorbidities, leading to higher mortality rates (13).

Lifestyle assessment

Smoking influences the body's inflammatory response through increased release of pro-inflammatory factors. In addition, smoking stimulates oxidative stress, which induces systemic inflammation. Smoking is also associated with immunosuppressive effects, reducing the patient's resistance to infection (14). Given the reported effects of smoking on proinflammatory mediators, including TNF-alpha, interleukin 6 and 8, severe cases of sepsis with higher mortality in smoking patients have been described, due to the immunosuppressive influences of smoking. All these are making the host less able to fight infection (15).

Hwa Lee *et al*. showed that the incidence of sepsis was higher in active smokers (especially those who smoked more than 30 pack-years) than in former smokers and non-smokers (16).

Obesity - a clinical condition in which weight is significantly greater than recommended (body mass index (BMI) > 30 kg/m^2, according to the World Health Organization definition) is usually attributed to excessive fat accumulation in the body. Statistically, it is involved in the pathophysiology of many diseases, impacting on global health (17).

Currently, the relationship between obesity and sepsis is incompletely elucidated. On the one hand, some studies show that obesity increases the risk of sepsis or other acute infections (17,18). On the other hand, study findings illustrate the *obesity paradox* for which the mortality rate from sepsis in obese patients is lower than in similar patients with lower BMI. (19, 20). The concept of obesity paradox is explained by three pathophysiological hypotheses: a) excess adipose tissue and stored energy support the catabolic state induced by sepsis; b) the systemic inflammatory response may be different in obese patients than in normal weight patients, with an important role for visceral fat, which is associated with metabolic syndrome; c) adipocytes may be immunomodulatory, as obese patients have lower levels of proinflammatory cytokines than expected during severe infections (21, 22). Increased levels of lipoproteins and adipose tissue may also bind and inactivate lipopolysaccharides, which are involved in septic pathophysiology. Also, levels of the proinflammatory cytokine interleukin-6 are reduced in obese patients (23, 24).

Patients with sepsis are affected by coagulation disorders. They present an increased risk of thrombotic complications, which may vary from microvascular changes such as disseminated intravascular coagulation to venous thromboembolism in the form of deep vein thrombosis or pulmonary embolism. The pathophysiological processes in sepsis occur simultaneously, and the correlation between the mechanisms of coagulation and inflammation has been described by Engelmann and Massberg as *immunothrombosis*. This explains the complex and mutual interaction from which the activation of the coagulation cascade triggers the immune system and innate immune cells stimulate thrombus development (25).

Prolonged bed rest and lack of physical activity have significant consequences for the body's well-being, with disorders on the musculoskeletal, cardiovascular, respiratory, integumentary and cognitive systems (26).

Identification of invasive medical devices

The use of any type of invasive device increases the risk of infection. Most commonly used are intravascular catheters (peripheral and central), urinary catheters, endotracheal catheters. The risk of infection increases with the duration of exposure. It has been estimated that approximately 50% of urinary tract infections (UTIs) are associated with the presence of a urinary catheter, and up to 64% of bloodstream infections are associated with a vascular device (27). In our study there were also patients with sepsis, who had urinary catheters, but sepsis was not due to urinary causes but to the skin one, an aspect highlighted by the bacteriological examination from the skin lesion (one of the inclusion criterion).

Clinical examination of skin lesions

Acute infectious dermatoses most of the time start suddenly with soft tissue erythema, induration, local heat, pain, erosions or fissures, to which general symptoms such as fever, deterioration of vital functions can be added, up to multiple organ dysfunction in case of septic complications. Detailed analysis of local and systemic manifestations allows a correct diagnosis to be made and appropriate treatment to be rapidly instituted (7). In the studied groups, skin semiology revealed the presence of lesions with loss of tissue: erosions, fissures, ulcerations, excoriations, bullae/blisters. These completed the clinical picture of dermatological pathologies such as venous ulcers, microbial eczema, cellulitis, erysipelas, pemphigus, pemphigoid, polymorphic erythema, Steaven Johnson's disease, erythroderma.

The appearance of lesions with loss of tissue and their superinfection are the main clinical warning signs of cutaneous sepsis. Dynamic observation and assessment by the dermatologist allow therapeutic measures to be applied before sepsis occurs (fig. 5). These could be essential steps in the clinical algorithm of the skin changes.

Identification of the microbial agent in skin lesions

Any disturbance of the skin microbiome exposes the skin to microbial invasions - some of these concerns the superficial layers (ecchymoses, boils, folliculitis, etc.), others progress deeper, as in cellulitis, erysipelas, erythroderma, necrotizing fasciitis. Pathogen agents enter into the skin through hair follicles or through minor skin lesions with loss of tissue. Among common bacterial species there are penicillin-sensitive or penicillin-resistant S. aureus and group A Streptococcus β- hemolytic (28). Streptococcal species are involved in the pathogenesis of cutaneous infections through activation of superantigen T cells by streptococcal toxins, followed by a specific T cell response (29). Some bacterial infectious agents can induce an altered immune response that underlies the etiopathogenesis of autoimmune diseases, such as systemic sclerosis. The presence of increased titers of specific autoantibodies causes immunosuppression (30, 31).

Assessment of comorbidities

Associated pathologies have been carefully assessed as they influence the progression of skin infections and sepsis, both by accelerating inflammatory mechanisms and by involving coagulation mechanisms. The patients of our study presented a series of typical representative systemic diseases, which can be systematized into cardiovas-

cular, metabolic, neurological, respiratory, renal and genital diseases.

Acute inflammatory mechanisms of infections increase the risk of cardiovascular events. The activation of inflammatory molecules and platelets, increased inflammation in atheromatous plaques, endothelial dysfunction and increased activity of the sympathetic nervous system with catecholamine release contribute to the electrical instability of the heart and atherosclerotic plaque but also to a concomitant hypercoagulable state (32).

Data published by Bohula *et al*. illustrate that the most common cardiovascular comorbidities in patients with sepsis are heart failure, valvular disease, arrhythmias and ischemic heart disease (33). Consistent with this, our study highlights the increased proportion of hypertension, atrial fibrillation, heart failure and obliterating arteriopathy of the lower limbs for patients with cutaneous sepsis.

Acute skin infections of patients with diabetes include multiple diseases, from folliculitis to more severe infections involving deep tissues, diabetic foot and sepsis. They are the leading cause of morbidity and mortality. Poor blood glucose control is closely correlated with infectious risk. Elevated glucose levels are associated with tissue damage, through irreversible, non-enzymatic glycation of proteins, impaired immune response and generation of reactive oxygen species, which play a critical role in cellular homeostasis (34).

The results of our study illustrate that diabetes is a common comorbidity in patients with cutaneous sepsis, particularly for type 2 diabetes. However, the impact of diabetes on the evolution and prognosis of sepsis is controversial, and there is sufficient argument to confirm that the presence of diabetes does not increase the risk of mortality in patients with sepsis, but is associated with an increased risk of acute renal failure (35).

Altered mental status in patients with sepsis is an acute alteration in cognitive and psychological function and level of consciousness, which may manifest as confusion, behavioral changes and changes in alertness. Sepsis-associated encephalopathy (SAE) is a complex neurological syndrome contributing to diffuse brain dysfunction. It can manifest itself through a range of symptoms, from agitation and restlessness to delirium and coma. Although SAE appears to be a reversible pathophysiological process centered on systemic inflammation, there is sufficient evidence that sepsis can cause structural brain damage and long-term neurological consequences (36).

The current definition of sepsis (sepsis-3), clarifies the altered mental status of sepsis, measured by the Glasgow Score (GSC), which is found in both the Sequential Organ Failure Assessment (SOFA) score and the Quick SOFA (qSOFA). The SOFA score is used to assess organ failure, which evaluates the degree of respiratory, renal, cardiovascular, neurological, hepatic and hematological impairment. The qSOFA is used in the emergency department for the rapid calculation of organ failure, considering respiratory rate, hypotension and Glasgow score (37, 38).

Other concomitant systemic conditions that patients with sepsis presented with were renal and genital diseases such as lower urinary tract infections and chronic kidney disease. Although the percentage was 10.3% for respiratory comorbidities, these included chronic obstructive pulmonary disease (COPD) and asthma.

Clinical algorithm for cutaneous lesions

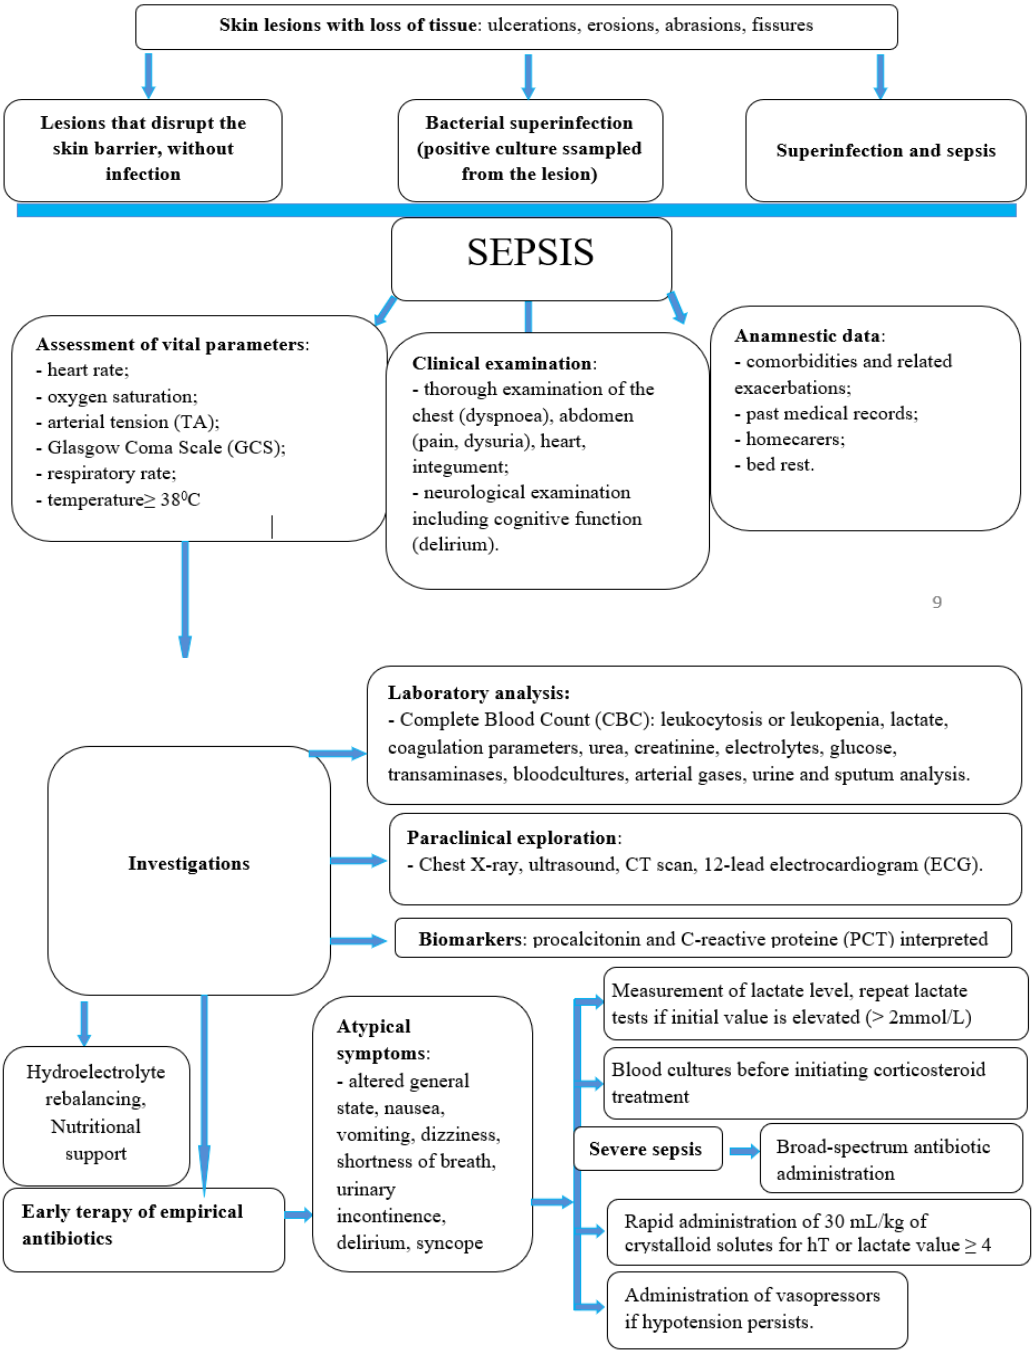

Fig. 5. Clinical algorithm for skin lesions

CONCLUSIONS

The skin, through changes related to the disruption of the skin microbiome, provides many clues to severe conditions, which can be prevented by strategies targeted on early miscellaneous skin disorders. A detailed analysis of over 400 patients with acute skin infections admitted to the dermatology clinic showed that minor skin disorders (fissures, erosions, etc.) can lead to serious systemic complications with a negative impact on life quality. A simple but careful inspection of the skin surface performed by the dermatologist provides useful information in assessing the extent and depth of the lesion, local microcirculation and hydration. Erosions, fissures, excoriations are skin lesions with loss of tissue, which were present on the patients included in the study (one of the inclusion criteria). They represent the coutaneous-onset sepsis and therefore the proper management of these lessions has an important role in preventing sepsis. The number of skin lesions, their surface are important dermatological characteristics, but the severity of the acute infection depends on the aggressiveness of the bacterial agent which invades the body, depends on the host's immunity and associated pathologies. Correlation with lifestyle and systemic symptoms - cardiovascular, metabolic, neuropsychiatric - are essential prognostic indicators in cutaneous sepsis. The usage of the qSOFA score in dermatological practice is an effective and rapid measure for detecting cutaneous sepsis when correlated with the cutaneous semiology. Most of the time skin lesions are not just a dermatological condition, but are the clinical expression of internal organ imbalances. The dermatologist's involvement in the management of the critically ill patient, who also associates cutaneous lesions, is necessary in order to establish their primary or secondary nature and makes an important contribution in differentiating cutaneous sepsis from other types of sepsis.

ARTERIAL STIFFNESS ASSESSMENT IN ABDOMINALLY OBESE INDIVIDUALS: INSIGHTS FROM CLINICAL OBESITY PHENOTYPES (Abstract): Precise cardiovascular risk assessment remains challenging, especially amidst the dynamic interplay of factors like abdominal obesity, inadequate physical activity and imbalanced diet. This study aims to assess subclinical atherosclerosis in apparently healthy individuals with excess weight, using arterial stiffness as a parameter for cardiovascular risk assessment. **Materials and methods**: A cohort of 67 patients aged 35-75 years, without any prior atherosclerotic pathology, with abdominal obesity and no known chronic illnesses, underwent evaluation. The cohort was stratified based on obesity (BMI≥30kg/m^2), metabolic syndrome (MetS NCEP-ATP III criteria), BMI class, total or trunk adipose tissue percentage, and clinical phenotypes of obesity (metabolically healthy obese - MHO, metabolically unhealthy obese - MUO, metabolically healthy non-obese - MHNO, metabolically unhealthy non-obese - MUNO), where unhealthy is defined by the presence of MetS. Biochemical analysis was performed to assess glucose, TG and HDL-c levels, aiming to detect potential undiagnosed cases of MetS. Adiponectin and leptin measurements were also performed. Hologic QDR Delphi A determined whole body composition with dual-energy-X-ray absorptiometry (DEXA) and Arteriograph® Tensiomed measured parameters of subclinical atherosclerosis. **Results**: Pulse wave velocity (PWV) values did not significantly differ across study groups, including obese versus non-obese individuals, clinical phenotypes of obesity, presence or absence of MetS, groups defined by BMI class, or adipose tissue percentages. Nevertheless, participants with excess weight or with MetS presented lower AIXa values. The groups that did not present MetS (obese and non-obese) showed the highest proportion of patients with PWV values under the age-adjusted theoretical threshold (46.15% and 44.4%, respectively), suggesting a potentially lower vascular age than the biological one. Conversely, the groups with MetS (obese and non-obese) had smaller percentages (26.67% and 16.66%, respectively). Around 30% of patients across clinical obesity phenotypes exhibited PWV values exceeding the theoretical threshold, but under 10 m/s. **Conclusions**: AIXa values are lower in the presence of MetS and in higher BMI subjects, whereas PWV values do not change significantly. Healthy obese individuals demonstrate a vascular age similar to the healthy non-obese group, suggesting enhanced cardiovascular protection. On the other hand, arterial stiffness is reported in a higher percentage of subjects that present MetS (obese or non-obese) compared to subjects without MetS, even though the syndrome is at an early stage. **Keywords**: OBESITY, ADIPOSE TISSUE, ARTERIAL STIFFNESS, SUBCLINICAL ATHEROSCLEROSIS, METABOLIC SYNDROME.

INTRODUCTION

Chronic inflammation, a key feature of the pathophysiology of obesity, is associated with increased arterial stiffness, along with other known cardiovascular risk factors including age or systolic blood pressure (1-3). Nevertheless, studies are conflicting concerning the relationship between adipose tissue and vascular rigidity. Several analyses reported higher pulse wave velocity (PWV) values in patients with obesity measured by BMI or trunk adiposity (4-6), while other studies support the inversed relationship, commonly referred to as the "obesity paradox". Without any doubt, obesity as defined by BMI increases the risk of cardiovascular events. However, this does not consider the percentage of whole-body or trunk adipose tissue, nor the visceral adipose tissue. Therefore, this seemingly paradoxical relationship may be explained by the fact that BMI primarily reflects lean body mass rather than adiposity and the latter is a more robust predictor of cardiovascular mortality and morbidity (7).

After a cardiovascular event a trend toward better prognosis has been observed in the overweight and obese population, linked to the same phenomenon of obesity paradox (8-10). Vascular function has been shown to be unexpectedly better in severely obese individuals compared to moderate or even normal-weight subjects. Even though they exhibit high inflammation, they may still experience partial protection against atherosclerosis, and one possible explanation is enhanced mobilization of endothelial progenitor cells (11).

Accurate estimation of cardiovascular risk remains a challenge, particularly in the context of dynamic changes in metabolic pathways influenced by the presence of modifiable factors like smoking, low dietary intake of fruits and vegetables, insufficient physical exercise, abdominal obesity, diabetes, hypertension, dyslipidemia or non-modifiable factors like age, sex, personal or family history of cardiovascular disease, ethnicity, genetic evidence. This study aims to examine the relationship between arterial stiffness and different measures of obesity in apparently healthy subjects, with no known chronic diseases, in order to reduce at a minimum the bias of factors.

MATERIALS AND METHODS

This prospective study was conducted over a two-year period and included 67 participants recruited based on the following criteria: no history of chronic disease and no prior atherosclerotic events. Pregnant women and individuals who declined to provide informed consent prior to enrolment were not included in the study. All investigations were undertaken by trained personnel within the same clinical and laboratory setting, utilizing standardized equipment and analytical methods throughout the study duration.

Anthropometric parameters were measured using a tape meter at the umbilical (waist circumference) and greater trochanter (hip circumference) level. Whole body composition measurements were assessed with Dual-Energy X-ray Absorptiometry (DEXA) technique, using Hologic QDR Delphy A fan-beam (Hologic Inc., Massachusetts). The biochemical profile for each participant at the study was performed using the spectrophotometric method for

triglycerides, HDL-c and glucose, enzyme-linked immunosorbent assay (ELISA) for adiponectin and leptin, chemiluminescence technique for insulin.

Arterial stiffness was assessed in participants using the Arteriograph® Tensiomed (Budapest, Hungary). The following parameters were measured: pulse wave velocity (PWV), augmentation index (AIXa), aortic pulse pressure (PPao), aortic systolic blood pressure (SBPao), mean arterial pressure (MAP), reflection time (RT), and ejection time. The device's cuff was positioned on the dominant arm, and the length of the aorta up to the iliac bifurcation was estimated based on anthropometric measurements (the distance between the pubic symphysis and the suprasternal notch) (12). To ensure standardized conditions, participants were instructed to rest quietly in a controlled environment prior to the examination, with no alcohol, tobacco or caffeine in the last 10 hours. Talking or movement during measurements was not allowed (13). After recording blood pressure, the device applied an additional pressure of 35 mmHg to facilitate the analysis of pulse wave reflections. The accompanying software calculated the PWV and other hemodynamic parameters.

The study cohort was divided in groups dependent on the obesity status, MetS status and body composition. Four obesity clinical phenotypes were described: metabolically healthy obese (MHO) or non-obese (MHNO) and metabolically unhealthy obese (MUO) or non-obese (MUNO). The obesity status was present if participants presented BMI≥30 kg/m^2. The metabolically unhealthy status was present if the participant presented MetS, which was defined in patients with waist circumference > 88 cm (women) / 104 cm (men) and that presented at least 2 criteria: glucose ≥ 100 mg/dL, HDL-C < 40 mg/dL (men) / < 50 mg/dL (women), TG ≥ 150 mg/dL, TAS/TAD ≥ 130/85 mmHg (14).

The process of data was handled with Microsoft Excel v.16.64 (Microsoft Corporation, USA) and *SPSS version 23.0* (IBM Corporation, USA). Kolmogorov-Smirnov/ Shapiro-Wilk tests were used for assessing data distribution. For normally distributed variables, values of the mean±standard deviation were reported and for non-normally distributed variables, values of the median, along with quartiles. Categorical variables are reported as percentages. For comparative analysis between continuous variables, the independent parametric test one-way ANOVA was used for a normal data distribution and the non-parametric test Mann-Whitney U for a non-normal distribution. For correlation analyses, the Pearson, Kendall's tau-b and Spearman correlation tests were performed. Values of $p<0.05$ were considered statistically significant.

RESULTS

This study included 67 apparently healthy but overweight patients, in whom subclinical atherosclerosis indicators were measured to assess the cardiovascular risk. Among the arterial stiffness parameters, only AIXa, RT, MAP and ejection duration showed a normal distribution according to Shapiro-Wilk test. Table I presents the general data of the parameters evaluating the biochemical profile and subclinical atherosclerosis in the study group. The comparative analysis of the PWV value

between groups did not reveal statistically significant differences, but significant differences were observed regarding the AIXa values (fig. 1).

Within the entire sample, of all the anthropometric, biochemical and adipose tissue-related parameters, PWV correlated only with the waist-to-hip ratio. Conversely, AIXa was negatively associated with anthropometric parameters (tab. II).

TABLE I.

Descriptive parameters of the study group

Parameter	Mean±S.D.	Min	Max	Median (Q3-Q1)
Parameters of subclinical atherosclerosis				
PWV	9.90±1.76	7.2	14.9	9.7 (2.2)

From the entire cohort of patients, 61.20% exhibited normal PWV values. Within this subgroup, nearly half presented values below the theoretical PWV, derived from a database of approximately 10,000 measurements from a Central European population. Table III details the distribution of patients and corresponding percentages, stratified by clinical obesity phenotypes.

No statistically significant differences in biomarkers, anthropometric measurements, or adipose tissue parameters were observed between patients with normal PWV values and those with PWV values exceeding 10 m/s within the MHO, MHNO, MUNO subgroups. Statistically significant data for the MUO subgroup are presented in table IV.

TABLE III.

Comparative analysis of real PWV with theoretical PWV across study groups

	MHO	MUO	MHNO	MUNO	Total
Patients with PWV < theoretical value	6	5	4	4	19
Patients with PWV > theoretical value. but under 10 m/s	3	11	3	5	22
% patients with PWV > theoretical value. but under 10 m/s	33.33%	68.75%	42.86%	55.56%	53.66%

DISCUSSION

The present study reports new data on the association between the four obesity clinical phenotypes and cardiovascular risk, also exploring the correlations between markers of subclinical atherosclerosis and

adiposity parameters. Arterial stiffness, as assessed by PWV, AIXa, and PP, is an independent risk factor for cardiovascular mortality (15). Our results suggest that while PWV and PP do not significantly discriminate between groups regardless of obesity status, clinical phenotype of obesity, presence of metabolic syndrome, or body composition, AIXa reports statistically different values. These findings emphasize the need for further studies to clarify the role of AIXa in the assessment of cardiovascular risk. This marker is not as well studied as PWV, but it is associated with known risk factors for cardiovascular disease (16, 17).

In obesity, AIXa has been reported to have both elevated (18) and decreased values (19, 20). In our study, obese patients overall have lower AIXa values than non-obese patients, as well as those with MetS compared to those without MetS. In particular, at the clinical phenotype level, only MUO report significantly lower values than MHNO and MUNO. Consequently, we can assume that obesity together with MetS represents an association that reports low AIXa values in the studied population. Our findings are contrary to those of several previous investigations included in the systematic review and meta-analysis performed by Li P., *et al.* that showed increased PWV and AIX values in obese or overweight subjects (21). Nevertheless, our results are consistent with other investigations that emphasize a better outcome after percutaneous coronary interventions in subjects with high BMI (22) or even improved vascular function in healthy but obese individuals (11).

The decrease in AIXa values could be explained by the effect of insulin. It has a vasodilatory role by stimulating nitric oxide synthesis (23, 24), leading to increased vascular wall elasticity and altered aortic wave reflection. Several studies have reported lower arterial stiffness in obese and/or MetS patients compared to normal-weight patients, due to insulin (25-28). At the same time, metabolic insulin resistance may have vascular effects through non-enzymatic glycation processes leading to collagen cross-linking or through sympathetic activation and smooth muscle cell proliferation, leading to stiffness (29, 30). We cannot establish a cause-and-effect relationship in our study, but insulin and HOMA-IR values are higher in obese patients, with MetS or MetS clinical phenotypes. We can consider the acceptable quality of endothelial function observed in these patients as a consequence of the diagnosis of an early stage of MetS in the study group, with minimal metabolic changes, given that the patients included in the study were apparently healthy. Moreover, we must also consider the fact that the AIXa parameter is influenced by heart rate and does not represent such a reliable parameter of vascular stiffness as PWV.

In the studied population, PWV value is associated with MetS and not with obesity, since the prevalence of patients with abnormal PWV values is higher in MetS patient groups, regardless of the presence of obesity. Recent studies have demonstrated that there is no association between PWV level and obesity (31, 32), but a significant impact of MetS on PWV was confirmed in a prospective, multicenter study with patients from 18 European countries (33). Furthermore, another study identifies PWV as a more effective parameter than SCORE-2 or other grids that measure the risk of cardiovascular disease, to estimate vascular age in patients with MetS (34).

Adiponectin is lower in patients with

abnormal PWV values, although the percentages of total and non-adipose tissue at the trunk level show similar values to those of patients in the normal PWV group. Hypoadiponectinemia has been identified in coronary atherosclerosis and acute coronary syndrome and has been associated with increased arterial stiffness (35, 36).

Several studies have reported a higher cardiovascular risk in MUO patients than in MHO (37, 38). The MHO phenotype in our study presents the highest percentage of patients with PWV below the theoretical value, more precisely below the mean value corresponding to the patient's age. This result implies a lower vascular age than that associated with the patient's biological age, suggesting additional cardiovascular protection. A study conducted on 2,076 participants supports our results, concluding that the progression of arterial stiffness was not increased in MHO patients, contrary to the result obtained for MetS groups, where regardless of the presence or absence of obesity, the evolution of arterial stiffness was significantly unfavorable (39).

CONCLUSIONS

PWV values do not differ significantly in apparently healthy individuals with abdominal obesity, regardless of BMI, MetS, adipose tissue percentage or clinical obesity phenotypes. AIXa values are lower in the presence of MetS and in subjects with higher BMI, however its values are influenced by different factors and therefore it is not such a reliable parameter of vascular stiffness as PWV. Healthy obese individuals demonstrate a vascular age similar to the healthy non-obese group, meanwhile there is an important increase in the number of subjects with MetS-associated arterial stiffness, even though the MetS is at an early stage. Therefore, as long as healthy obese do not develop MetS, their vascular rigidity is considered more likely to be at the level of that for non-obese.

A QUALITATIVE STUDY ON THE CAUSES OF MEDICAL MALPRACTICE COMPLAINTS (Abstract): Medical malpractice complaints represent a genuine challenge for both medical and legal scholars. In recent years, there has been a notable increase in the number of complaints filed against physicians for alleged acts of medical malpractice. **Materials and methods:** To achieve our objective, we conducted a qualitative study in which data were collected through semi-structured interviews. The participants in our study were lawyers with experience in handling medical malpractice cases. **Results:** A total of 14 lawyers participated in the study. Thematic analysis of the collected data led to the identification of 9 main themes and 21 subthemes. The central focus of this article is the investigation of the causes underlying medical malpractice complaints. According to the lawyers interviewed, these causes include dysfunctions in the physician-patient relationship, professional errors, and systemic shortcomings. **Conclusions:** Our research indicates that the reasons behind medical malpractice complaints are multifaceted. The results of this study may serve as a foundation for developing strategies aimed at reducing the number of malpractice complaints in the healthcare sector. **Keywords:** MEDICAL MALPRACTICE, DOCTORS, LAWYERS, MEDICAL LIABILITY.

INTRODUCTION

The healthcare sector is considered a top priority within the broader framework of social concerns (1). In contemporary medicine, patients are increasingly regarded as active participants in the provision of care, holding both rights and responsibilities (2). According to the specialized literature, the causes underlying medical malpractice complaints are diverse, including misdiagnosis, procedural errors (3), and other similar factors.

Filing a complaint against a healthcare professional is viewed as a normal and legitimate mechanism in a democratic society. Although recent technological advancements in the medical field have been significant, the number of malpractice complaints against physicians continues to rise (4). Identifying the causes of medical malpractice complaints is of critical importance, as such insights can help reduce litigation within the healthcare system (5).

The aim of our study was to determine the reasons why patients file medical malpractice complaints against physicians.

MATERIALS AND METHODS

To achieve the objectives of our research, we employed a qualitative methodology, with data collected through semi-structured interviews. The target population consisted of lawyers who had handled at least one case involving a medical malpractice complaint.

Both male and female lawyers participated in the study, regardless of their years of professional experience. Prior to participation, the lawyers were informed about the purpose, objectives, and procedures of the study, and each provided written informed consent.

The interview began with introductory questions related to the participants' legal specialization, their motivation for choosing this area of practice, as well as questions concerning their experience in handling medical malpractice cases. In addition to these, the interview included 19 open-ended questions. Among the topics explored were the reasons patients file complaints against physicians, as well as the lawyers' perspectives on alternative methods of dispute resolution in medical malpractice cases.

The interviews were fully transcribed, and the data obtained were analyzed using NVivo 14 software (trial version). The responses were grouped into nine areas of interest, which were initially coded through a review of the interview transcripts. These codes were subsequently organized into subthemes. The subthemes were identified based on their frequency of occurrence among multiple participants. Responses were labeled with the letter "A" followed by Arabic numerals corresponding to the order in which the interviews were conducted.

This study was approved by the Research Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy of Iași, through Decision No. 135/23.01.2022.

RESULTS

1. Causes of Medical Malpractice Complaints

In Romania, there are no predefined legal grounds for which a physician can be accused of medical malpractice. However, judicial practice has identified several common causes of malpractice complaints, including misdiagnosis, incorrect treatment, failure to intervene, and so on.

The lawyers who participated in our interviews provided detailed insights regarding both the physician-patient relationship and the broader systemic issues within the healthcare sector. Based on their responses, two main subthemes emerged: one related to the therapeutic relationship and the other concerning systemic dysfunctions in the medical system.

1.1. Dysfunction in the Physician-Patient Relationship

Physicians represent a cornerstone of the healthcare system, alongside other professionals involved in medical care. In the course of their daily activities, they come into contact with a significant number of individuals, each of whom is affected by a medical condition. The main relational issues identified by the interviewed lawyers that lead patients to file complaints against physicians revolve around a breakdown in communication.

The physician-patient relationship is fundamentally based on mutual trust and

respect. In fact, the Medical Code of Ethics issued by the Romanian College of Physicians states, under Article 14 titled "Prior and Appropriate Information of the Patient," that "The physician shall request and obtain informed consent only after the person concerned, or the person legally entitled to give consent for the medical intervention, has been adequately informed about the purpose and nature of the intervention, as well as the foreseeable and generally accepted risks and consequences, in accordance with medical standards."

Similarly, Article 8 of the Patient Rights Law No. 46/2003 stipulates: "Information shall be communicated to the patient in a respectful and clear manner, minimizing the use of medical terminology. If the patient does not understand the Romanian language, the information shall be provided in their native language or a language they understand, or, if necessary, through alternative means of communication."

In practice, when it comes to informing the patient, legal provisions are clearly in place. This means that failure to comply with these requirements may result in disciplinary or legal sanctions for the physician. In this regard, issues related to lack of transparency and communication breakdowns were frequently reported by the lawyers we interviewed.

"This lack of transparency is about the fact that, in the medical field, no one really has time to explain things like, 'we're about to perform a procedure that involves certain risks, certain issues.' They just put that informed consent form in front of you, which obviously needs to be signed. They rely on the assumption that the patient will read it… but let's be honest-out of ten patients, nine don't read what they sign; they just want the medical problem to be resolved. I think it should be like in the movies, where the doctor always explains to the patient, 'Look, there are some risks involved; we want you to make an informed decision.' Basically, that's what informed consent is supposed to mean, but expressed in a much more accessible, down-to-earth way that everyone can understand. Many people who come to the hospital or to the doctor don't have a formal education, they don't understand medical terminology, so it's absurd to just say, 'Here's the paper, you signed it, we're no longer responsible.'" (A2)

"There are cases where the patient's next of kin or family members are completely unaware of what's happening with the patient, and that's very… maybe it has some legal justification to a certain extent, but it's really hard to explain to someone that it's okay not to know anything about their mother or father who is in the hospital." (A2)

"After an error happens-or is suspected to have happened-or when the treatment doesn't yield the expected outcome, or there's disappointment regarding the result, the patient or family tries to contact the doctor or the medical facility. And at that point, the doctor shuts down all communication. In general, 90% of cases are like this. They stop responding to patients, or if they do meet them, they immediately start saying it's not their fault. They're unable to look at the situation from the perspective that they might have made a mistake. This violation of the patient's right to be informed-even after the medical act has taken place, about what happened and why-is deeply harmful. It's a non-material value that gets violated, and this happens in 99.9% of cases. When patients

hire us, I ask them: 'Why?' And they tell me, very clearly, 'I called, they wouldn't answer. They told me to stop calling, to do whatever I want.' It's a violation of human dignity, and that is what actually drives them to move forward with legal action." (A6)

1.2. Professional Errors

According to the opinions expressed by the study participants, another significant cause of medical malpractice complaint is the professional error committed by the physician.

"Patients are dissatisfied with the quality of medical care and with the refusal to provide medical assistance." (A9)

"In this case, medical protocols were violated, and the doctor essentially confused one illness for another. My client was repeatedly treated for adnexitis and pelvic inflammatory disease. But in reality, she had cancer. The symptoms are similar, but the most serious mistake the doctor made was that-after about seven hospitalizations-on the final lab report, the laboratory personnel explicitly recommended further in-depth testing. The doctor failed to inform my client about this and did not refer her for the additional tests." (A14)

There is no medical system in which those practicing within it do not make mistakes, regardless of how advanced or efficient that system may be. More importantly, the core issue does not lie in attempting to eliminate all errors-which is virtually impossible-but rather in how the consequences of such errors are managed and addressed.

1.3. Deficiencies in the Healthcare System

Other causes of complaints filed by patients are related to hospitalization conditions. The state of hospital infrastructure appears to contribute significantly to patients' dissatisfaction, many of whom hold physicians accountable for the overall situation. Although substantial investments have been made in Romania's healthcare system in recent years, these efforts have not been sufficient to meet patient expectations or ensure a satisfactory level of care.

"They [the patients] are primarily dissatisfied with the hospital conditions." (A4)

DISCUSSION

1. Causes of Medical Malpractice Complaints

Medical malpractice complaints can be filed by any individual, as the legislator grants patients the freedom to exercise this right. From a legal standpoint, there are no sanctions imposed on individuals who choose to submit such complaints.

To better understand the magnitude of medical malpractice causes, attention should be given to a study conducted in 2010 in the United States, which reported that, by the end of 2008, the Physician Insurers Association of America (PIAA) database contained information on approximately 239,756 resolved malpractice claims filed between 1985 and 2008.

The same study highlighted the most common medical errors, which included diagnostic mistakes, lack of physician knowledge, failure to properly monitor the patient, medication administration errors, failure or delay in referring patients to a specialist, failure to recognize adverse treatment effects, omission of clear instructions, and ineffective communication with the patient (6, 7).

1.1. Dysfunction in the Physician-Patient Relationship

The physician-patient relationship represents a key aspect of our research. The use of communication techniques that facil-

itate interaction between doctor and patient may be a decisive factor distinguishing physicians who have been subject to malpractice complaints from those who have not-primarily due to the loss of patient trust resulting from poor communication (8).

Effective communication between physicians and patients directly influences patient behavior and reduces the likelihood of filing medical malpractice complaints (9). This idea is also supported by the participants in our study, who indicated that one of the main causes of malpractice complaints is indeed the dysfunctionality of the physician-patient relationship.

Another viewpoint found in the specialized literature emphasizes that, in the modern world, medical malpractice complaints are less often rooted in the quality of care provided, and more frequently stem from the nature of the relationship between the two key actors in medical care-the physician and the patient (10). A lack of communication skills on the part of the physician increases the probability that the patient will file a complaint, regardless of whether a medical error actually occurred (11).

Similarly, a point highlighted by participants in our study is that patients tend to file complaints against physicians they do not feel a personal affinity with, as they often experience a sense of being ignored. Consequently, when a healthy, trust-based relationship is established between physician and patient, it serves as an important preventive factor against potential complaints (12). Moreover, a relationship built on trust necessarily involves effective communication, which strengthens the patient's sense of being respected-ultimately reducing the likelihood of initiating a malpractice claim (13)

1.2. Professional Errors

In line with the perspectives expressed in the specialized literature, the most common causes of medical malpractice are diagnostic errors, as well as delays in establishing a diagnosis (14). The literature, consistent with the views of the participants in our study, emphasizes that professional errors-particularly misdiagnosis-rank as the primary reason for filing medical malpractice complaints (15).

This finding is further supported by another study indicating that among the most frequent reasons patients are encouraged to file complaints against medical personnel are misdiagnosis, improper execution of medical procedures, and medication errors (16)-all of which fall under the category of professional mistakes. A separate study conducted in 2012 demonstrated that medical errors occurred both during the anamnesis phase and during the period in which the patient was under clinical observation (17).

1.3. Deficiencies in the Healthcare System

According to the participants in our study, one of the frequent reasons for filing medical malpractice complaints is represented by systemic shortcomings. This observation is supported by the specialized literature, with studies indicating that certain healthcare systems face ongoing challenges related to patient safety and the quality of care provided (18).

The literature further suggests that insufficient investment in the healthcare system can lead to medical errors, which undoubtedly reflect structural deficiencies within the system (19). Additionally, research shows that one of the causes for filing medical malpractice complaints is the violation of regulations by healthcare insti-

tutions (20). For example, a study conducted in the United States estimates that between 44,000 and 98,000 hospital deaths annually are attributable to medical management issues (21), which supports the claims made by participants in our research. Moreover, an important insight derived from another study indicates that harm resulting from "error," in its broadest sense, also encompasses systemic issues related to the organization and delivery of healthcare services (22)

CONCLUSIONS

Our research indicates that the underlying reasons for medical malpractice complaints are complex. Thus, patient complaints filed against physicians are not solely based on clinical errors, but also stem from dysfunctional relationships between doctors and patients, as well as from broader issues affecting the healthcare system as a whole.

The findings highlight the need for physicians to pay particular attention to the way they communicate and interact with patients, as this significantly influences the likelihood of a complaint being filed. Even though our national healthcare system is not among the most advanced globally, medical professionals continue to make substantial efforts to provide healthcare services that meet international standards.

The results of our study can serve as a foundation for developing strategies aimed at reducing the number of complaints in the medical sector.

CONFLICT OF INTEREST AND FUNDING

COMPARATIVE SURGICAL APPROACHES FOR EARLY-STAGE HEPATOCELLULAR CARCINOMA. A SINGLE-CENTER EXPERIENCE (Abstract): Hepatocellular carcinoma (HCC) remains a major global health concern, ranking among the top causes of cancer-related mortality. This study aims to assess and compare the outcomes of three curative surgical approaches-hepatic resection (HR), radiofrequency ablation (RFA), and liver transplantation (LT)-in patients with early-stage HCC. **Materials and methods:** We conducted a prospective analysis of 105 patients with BCLC stage 0-B HCC treated between 2015 and 2020 at a tertiary center in Romania. Patients were divided into three treatment groups: Group I (n=64) underwent HR, Group II (n=29) received RFA, and Group III (n=12) underwent LT according to Milan Criteria. Baseline liver function, tumor characteristics, operative details, and postoperative outcomes were recorded. The HR group was further stratified by transection technique (Habib device vs. crush-clamping). **Results:** The mean age differed significantly across groups (p=0.013), with LT patients being younger. Child-Pugh class A was predominant in HR (84.38%) and RFA (72.41%) groups, while B and C were more frequent in LT. Blood loss was significantly lower with the Habib device compared to crush-clamping (p=0.003). No recurrence was recorded in the LT group during follow-up, while recurrence rates were 56.52% for RFA and 31.67% for HR (p=0.003). The overall postoperative complication rate did not differ significantly among groups. Early mortality rates were 6.25% (HR), 10.34% (RFA), and 8.33% (LT). Our findings suggest that all three treatment modalities can be effective for early-stage HCC when selected according to patient-specific liver function and tumor burden. HR and RFA remain viable first-line options in compensated liver disease, while LT provides the most durable oncologic outcomes but is limited by eligibility and organ availability. The use of the Habib device, may reduce intraoperative blood loss in hepatic resections. **Conclusions:** Hepatic resection and radiofrequency ablation remain valid treatment options for early-stage HCC in patients with well-compensated liver function, while liver transplantation offers the most favorable long-term oncologic outcomes when applied within established criteria. A multidisciplinary, patient-centered approach is essential to maximize survival and minimize recurrence in HCC management.
Keywords: HEPATOCELLULAR CARCINOMA, LIVER RESECTION, RADIOFREQUENCY ABLATION, LIVER TRANS-PLANTATION, BCLC STAGE, SURGICAL OUTCOMES.

Hepatocellular carcinoma (HCC) is the most prevalent form of primary liver cancer and represents a major global health burden, both in terms of incidence and mortality. According to the latest global cancer statistics, liver cancer ranks as the sixth most commonly diagnosed malignancy and the third leading cause of cancer-related deaths worldwide, accounting for over 840,000 new cases and more than 800,000 deaths annually (1). Among these, HCC constitutes approximately 75% to 85% of all primary liver malignancies (2). The burden of HCC is not uniformly distributed; its incidence is highest in East and Southeast Asia, sub-Saharan Africa, and increasingly in Western countries, where lifestyle-related liver diseases are on the rise (3).

The pathogenesis of HCC is closely linked to chronic liver injury and inflammation, with cirrhosis being the most significant risk factor (4). Cirrhosis often results from chronic hepatitis B or C infection, excessive alcohol consumption, nonalcoholic steatohepatitis (NASH), autoimmune hepatitis, or genetic conditions such as hemochromatosis (5). In recent years, a paradigm shift in the etiology of HCC has been observed. While viral hepatitis remains a dominant cause in endemic regions, there is an alarming increase in HCC cases associated with metabolic disorders, particularly NAFLD and NASH, in both developed and developing countries (6). This trend is anticipated to continue, with the declining incidence of HCV-related HCC due to the widespread availability of direct-acting antivirals (DAAs) being counterbalanced by a growing prevalence of obesity, insulin resistance, and type 2 diabetes (7).

Despite notable advancements in diagnostic modalities and therapeutic interventions, the overall prognosis of HCC remains dismal. The asymptomatic nature of early-stage HCC and the lack of universally adopted screening programs contribute to late diagnoses in many patients(8). Consequently, only a small fraction of patients is eligible for curative treatments at the time of diagnosis(9). The cornerstone of curative therapy in HCC comprises three main strategies: hepatic resection (HR), liver transplantation (LT), and local ablative therapies such as radiofrequency ablation (RFA) (10, 11). The selection among these modalities depends on a delicate balance between tumor characteristics (number, size, location, and vascular invasion), liver function reserve, performance status, and comorbidities.

The Barcelona Clinic Liver Cancer (BCLC) staging system is widely endorsed, especially in Europe and Latin America, as a comprehensive framework for stratifying patients and guiding therapeutic decision-making (12). The BCLC system classifies HCC into five stages (0, A, B, C, and D) and recommends treatment options accordingly. Curative approaches are typically reserved for very early (stage 0) and early-stage (stage A) disease, which includes patients with preserved liver function, a solitary lesion or up to three nodules less than 3 cm, and an absence of portal hypertension or vascular invasion. For such patients, HR, LT, and RFA are considered appropriate curative strategies (9).

Hepatic resection remains the first-line treatment for patients with a single tumor and preserved liver function (typically Child-Pugh A), especially when the tumor is located in a favorable anatomical position and sufficient functional hepatic reserve is maintained (13).

Modern surgical techniques, enhanced imaging modalities, and better perioperative management have contributed to decreased morbidity and mortality following liver resection. However, recurrence remains a significant challenge, with reported rates of intrahepatic recurrence ranging from 50% to 70% within five years postoperatively (14).

RFA, a minimally invasive technique, has gained widespread acceptance as an alternative to resection in selected cases. It is particularly suitable for small tumors (<3 cm), especially in patients unfit for surgery due to comorbidities or poor liver function. RFA offers the advantages of shorter hospitalization, lower complication rates, and repeatability. However, its limitations include incomplete tumor necrosis, the heat-sink effect in perivascular tumors, and higher recurrence rates compared to surgical resection (15, 16).

Liver transplantation is considered the ideal treatment for patients with early-stage HCC and advanced liver disease, as it simultaneously removes the tumor and treats the underlying cirrhotic liver. The Milan Criteria-defined as a solitary tumor ≤ 5 cm or up to three nodules ≤ 3 cm without vascular invasion or extrahepatic spread-have become the benchmark for selecting transplant candidates due to their association with excellent post-transplant outcomes (17). Several centers have proposed expanded criteria (e.g., UCSF, up-to-seven, and Toronto criteria), which may further extend access to LT while maintaining acceptable survival outcomes (18-20). Despite its benefits, LT is limited by organ shortage, waiting list mortality, and complex perioperative management. In countries with underdeveloped organ donation systems, such as Romania, access to transplantation remains restricted (21).

The clinical decision-making process in HCC is further complicated by the coexistence of tumor progression and liver dysfunction. Scoring systems such as the Child-Pugh score and the Model for End-Stage Liver Disease (MELD) score are commonly used to assess liver function and determine surgical candidacy (22). The Child-Pugh score, although widely used, incorporates subjective elements such as ascites and encephalopathy. In contrast, the MELD score is an objective, continuous variable based on serum creatinine, bilirubin, and INR, and is particularly useful in organ allocation for transplantation (23).

The role of advanced imaging modalities-contrast-enhanced ultrasonography, multi-detector CT, and liver-specific MRI-cannot be overstated in the accurate diagnosis and staging of HCC (24). These modalities not only guide treatment planning but also reduce the need for invasive biopsies. Nonetheless, biopsy remains necessary in cases of atypical imaging patterns or when differentiating HCC from cholangiocarcinoma or metastases is clinically relevant (25).

In the Romanian healthcare system, characterized by limited resources and evolving transplant infrastructure, treatment decisions are influenced by institutional capabilities and availability of therapeutic modalities. Our center, located in Northeastern Romania, represents a tertiary referral institution where HR and RFA have been established for over a decade, whereas LT was only introduced in 2016. This context presents a unique opportunity to evaluate and compare outcomes across all three curative modalities for early-stage HCC within a single center, using standardized staging and inclusion criteria.

Given these considerations, the present study aims to provide a comprehensive analysis of clinical outcomes associated with hepatic resection, radiofrequency ablation, and liver transplantation in patients with BCLC stage 0-B hepatocellular carcinoma. Furthermore, the study evaluates technical aspects such as blood loss, resection margins, ischemia times, and intraoperative incidents, thereby contributing to the refinement of surgical strategies in early-stage HCC.

MATERIALS AND METHODS

The study was assessed and approved by the ethics committee of the "Sf. Spiridon" County Clinical Emergency Hospital from Iasi (No. 479/07.10.2024), and written informed consent was obtained from all patients. A prospective analysis was conducted, related to 105 patients selected in our Department of General Surgery and Liver Transplantation between 2015 and 2020, for surgical treatment, for stages BCLC 0-B. The inclusion criteria were: age ≥ 18 y.o., primary malignant tumor (histologically proved or overt imaging and laboratory HCC criteria), no macroscopic vascular invasion, no extrahepatic extension.

The 105 patients were divided into 3 groups: Group I, 64 patients who underwent LR, with 2 subgroups: I A, to whom we used the Habib US device liver transection, I B to whom we used crush clamping transection technique, Group II, 29 patients who had RF, and group III, 12 patients who underwent LT, all fulfilling Milan Criteria. This last group has been considered since October 2016 when we started the LT program. None of the resection or RF groups presented with previous surgery or synchronous malignancies so that they received a primary surgery. In the LT group,5 patients had previously one or more seances of TACE.

Prior to surgery, all patients underwent an accurate clinical assessment, laboratory work-up and imaging evaluation, including thorax and abdominal imaging (US, contrast-enhanced CT, MRI with liver specific contrast agent), percutaneous biopsy. Diagnostic laparoscopy and biopsy were necessary for indeterminate lesions non-accessible to percutaneous biopsy. Data about age distribution, etiology of the underlying chronic liver disease, Child-Pugh score, αFP, number and distribution of the tumors were recorded for all patients.

Specific data included the type of hepatectomy, intraoperative blood loss, tumor histology, and study of the resection margin for the resection group, as well as the waiting time on the list, the number and size of the nodules and operative parameters (cold ischemia time, warm ischemia time, blood loss, intraoperative transfusions, intraoperative incidents) in the LT group. Postoperative morbidity, surgical revision, early postoperative mortality, tumor recurrence, distant metastases, survival and hospital stay were evaluated for the three groups.

RESULTS

The male/female ratio in the overall group was 74/31. Patient characteristics over the 3 groups are seen in table 1. The mean age was higher in the resection group and as predicted was the smallest in the liver transplantation group due to the limit of age on the waiting list (< 65 years). The etiology of the underlying liver disease was mostly alcoholic and viral for all the three groups. The HBV infection was more frequent in the resection group, but in the radiofrequency group the infection with

HCV had higher incidence. Less than 20% of the patient had antiviral therapy in the resection group and less than 10% in the other 2 groups (tab. I).

TABLE I.
Patient characteristics

No patients (%)		Group I (HR)	Group II (RF)	Group III (LT)	
		64	29	12

	C	2 (3.12)	1 (3.45)	5 (41.67)	
AFP n, (%)	1-9 ng/mL	29 (45.31)	7 (25)	9 (75)	Pearson-χ2 - χ2=9.396; df=4; p=0.052
	10-99 ng/mL	25 (39.06)	15 (53.57)	3 (25)	
	>100 ng/mL	10 (15.63)	6(21.43)	0	

The main symptoms encountered within the clinical presentation were: pain, weight loss, loss of appetite, asthenia and fever. Abdominal US identified suspect nodule/s in all cases (100%), which were further assessed as malignant / HCC by MDCT - 93.33% and MRI - 53.33%; PET-CT was used in 4 patients (3.8%) to exclude distant metastases. The percutaneous biopsy was performed in39 cases (37.14%) with non-specific or indeterminate imaging. In 21 patients (20%), laparoscopic biopsy was necessary.

For HR group, the type of resection, intraoperative blood loss and the study of the resection margin are presented in table 2, either for the use of Habib device transection technique or crush clamping procedure. The compared parameters revealed a statistically significance regarding the intraoperative blood loss between the Habib group and the crush clamping group (p= 0.003).

Twenty-nine patients underwent RF, by open approach -17 (58.6 %), laparoscopic - 10 (34.48%) and percutaneous - 2 (6.89%).

For the LT group, the waiting time on the list was 29-456 days (mean 177.5 days). The number of tumors were: single in 7 patients, two in 3 patients and three in 2 patients (mean number of lesions 1.58), with a maximal diameter of 15-50 mm (mean 24.16 mm).

Regarding the intraoperative parameters, cold ischemia time was 90 to 330 minutes (mean 206.25 minutes) and warm ischemia time 33 to 60 minutes (mean 41.25 minutes). The blood loss during the

LT procedure varies between 1800 mL and 9000 mL (mean 4908.33 mL).

The necessary of transfusion according to the intraoperative blood loss and intraoperative incidents are disclosed in table III.

RCM = red cell mass; PCC- prothrombin cellular concentrate; FFP: fresh frozen plasma

Tumor histology according to the pathology report for group I and III confirmed HCC in 71 cases representing 93,42% of 76 cases, the remaining cases being fibrolamellar carcinoma (3 cases in HR group) and intrahepatic cholangiocarcinoma (1 in HR group and 1 in LT group). All patients from group RF had a previous confirmation of HCC by biopsy.

Overall postoperative morbidity and the type of postoperative complication on each group are presented in table IV. The incidence of complications is not significantly different between the three groups (χ^2=0.533; df=2; p=0.766).

Surgical revision was required in the whole groupin5.71% cases, in6.25% cases in the resection group, 3.44% cases in the RF-ablation group and 16.67% in the LT group (χ^2=2,027; df=2; p=0,363).

TABLE IV.

Postoperative complications

Complications n, (%)	HR,19 (29.68%)	RF, 4 (13.7%)	LT 3 (25.00%)
Respiratory	10(15.62)	2 (6.89)	1 (8.33)
Liver failure	7 (7.81)	0 (0)	0 (0)
Ascites	12 (18.75)	2 (6.89)	3 (25.00)
Biliary fistula	3 (4.68)	0 (0)	0 (0)
Hemoperitoneum	2 (3.1)	1 (3.44)	1(8.33)
Liver abscess	1 (3.44)	0 (0)	0 (0)
Wound infection	8 (12.5)	0 (0)	0 (0)
Renal failure	3 (4.68)	1 (3.44)	1 (8.33)
MSOF	1 (3.44)	0 (0)	1 (8.33)

Mean hospital stay in groups LR/RF/LT was 12.63/6.69/28.58 days respectively. The difference was significant for groups II and III ($p<10^{-3}$).

Recurrence was significantly higher in the RF group (13 patients representing 56.52%) compared with HR group (19 patients -31.67%) (χ^2=11.575; df=2; p=0.003); no recurrence was noted in the LT group until the end of the follow-up

period. The mean interval until recurrence was 13.25±7.96 months.

Distant metastases were diagnosed in12 cases, representing 12.63% of patients of the whole study group, with the following location: lung - 6 cases (50%), bones - 4 (33.34%), both bone and lung and abdominal wall in one case each (8.33%). The mean period until diagnosis of distant recurrence was 13.33±5.68 months.

The overall early postoperative mortality (<30 days) was 6.67%, also higher in RF group (10.34%), compared with HR group (6.25%) and LT group (8.33%) (χ^2=1.506; df=2; p=0.471). The overall survival is presented in figure 2. The overall survival for the first two groups was influenced by the recurrence and the underlying liver disease, 49,9 months. For LT group, 11 patients were alive at the end of the follow-up period.

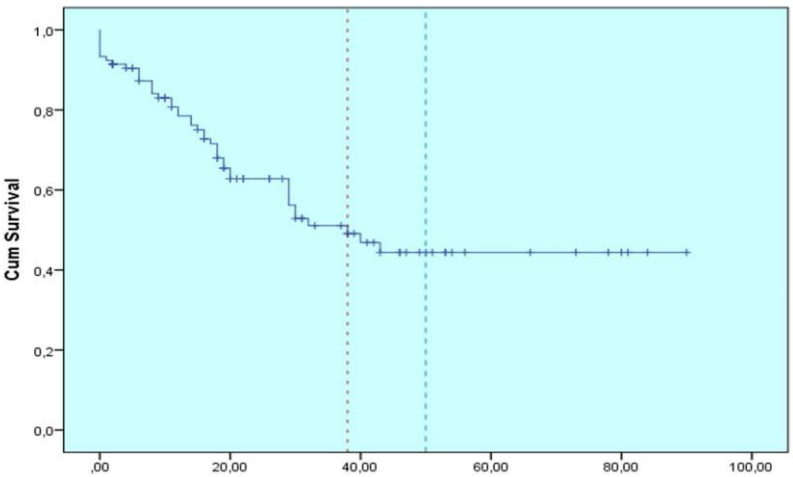

Fig. 2. Kaplan-Meier survival curve

DISCUSSION

Despite the steadfast progresses in the treatment of chronic liver disease, early tumor detection and oncological therapies, the HCC remains a challenge to early diagnose therefore the prognostic remains poor. About 85-90 % of all HCCs have a certain etiology, foremost the viral cirrhosis (26, 27). However, for the next few decades, a major shift is likely to appear in the etiology, with a decreasing of chronic hepatitis C disease, due to the fast spread of modern direct-acting antiviral drugs alongside a rise of non-alcoholic fatty liver disease (28).

In our series, the spectrum of etiology was dominated by metabolic cirrhosis and ethanol. Most of the patients in groups 1 and 2 in our series have Child-Pugh A score (84 % and 72 % in the HR and RF group respectively, unlike the LT group with 16 %. As consequence, most patients of the LT group had B and C Child-Pugh score (42 % of each). In Western Europe countries, the Barcelona Clinic Liver Cancer (BCLC) classification is the most widely employed prognostic staging system for HCC. It includes liver function, patient`s performance status and the extent of tumors and identifies 5 stages of disease (0, A-D) (9,29,30). All the patient in our series were included in stages 0-B BCLC (very early

and early disease).

Since the classical BCLC classification constitutes a landmark in decision-making approach, the BCLC classification-based therapy boundaries tends to blur. Hepatic resection represents the first-line therapy for hepatocellular carcinoma, with a 5-year survival rate exceeding 50%. However, postoperative outcomes are influenced by the presence of liver cirrhosis, requiring a parenchymal reserve of at least 40-50%, or by the multicentric nature of the tumor. The degree of fibrosis associated with liver cirrhosis is directly correlated with post-resection tumor recurrence (31, 32).

Liver resection should be the primary treatment option in patients with single HCC and well-compensated Child A cirrhosis (33, 34). Hepatic resection can be undertaken also in advanced HCC, RF is also applied in larger HCCs with good results (35). RFA represents a therapeutic option for elderly patients with multiple comorbidities, poor general condition, small tumor formations, or multicentric disease, as a single session can achieve complete ablation of lesions smaller than 3 cm with a 1 cm safety margin (36, 37). Multiple procedures can be performed in the case of large tumors (38).

Consequently, individual patient evaluation, biology of HCC and underlying liver disease understanding, are mandatory to achieve maximal oncological radicality without significantly endanger the liver function (Bruis J, WJG). It has been revealed that the 5-year survival excides 50% (39). According to the size and location, vascular invasion as well multifocal disease, segmentectomy, bisegmentectomy, sectionectomy or even major hepatectomy can be performed (40).

Major hepatectomy can be safely performed nowadays due to better understanding of the liver anatomy, advances in surgical instruments and refinements of surgical approaches (41). In our series, we used most commonly the anterior approach to avoid liver mobilization and rupture of larger tumors, by crush clamping technique when performing major hepatectomy, unless segmentectomy and bisegmentectomy, whenever we have used most commonly the 4 electrodes Habib device.

New therapies in hepatocellular carcinoma and the growing experience in liver transplantation and resection have led to the extension of transplant criteria beyond those defined by the Milan Criteria; however, this has been associated with an increased rate of tumor recurrence (42,43). In our study, all patients who underwent liver transplantation met the Milan Criteria, with no tumor recurrence recorded at 4 years.

Another essential aspect of HCC management is prevention, a factor that should play a central role in the overall treatment strategy. Prevention is primarily based on the control of modifiable risk factors, such as viral hepatitis and metabolic syndrome, which can significantly contribute to the development and progression of HCC (44).

The implementation of effective measures to prevent hepatitis B and C virus infections-through vaccination, screening, and antiviral treatments-can significantly reduce the incidence and severity of the disease (45, 46).

CONCLUSIONS

The management of Hepatocellular Carcinoma requires a personalized approach that balances treating the tumor with preserving the patient's liver function. Our findings confirm that treatment selec-

tion—whether resection, ablation, or transplantation-is critically dependent on the severity of the underlying liver disease. As the cause of HCC shifts from viral hepatitis to metabolic conditions, strategies for prevention and surveillance must also evolve. The future of effective HCC management lies in moving beyond rigid guidelines toward individualized plans crafted by a multidisciplinary team, pairing advanced therapies with a renewed focus on preventing the root causes of liver disease.

This two-pronged approach-advancing treatment while preventing initial disease-offers the greatest promise for reducing the global burden of this formidable cancer.

POSTOPERATIVE LUMBAR SPONDYLODISCITIS: INFLUENCE OF DISCECTOMY LEVEL AND COMORBIDITIES ON PAIN RELIEF AND HOSPITALIZATION DURATION (Abstract): Postoperative lumbar spondylodiscitis, although uncommon affecting approximately 3-5% of spinal disc surgeries remains a serious complication. Unlike primary vertebral osteomyelitis, this condition generally results from intraoperative contamination or unfavorable postoperative circumstances. The current study investigates the influence of comorbidities and other clinical parameters on the course and prognosis of postoperative spondylodiscitis occurring after lumbar disc herniation surgery. **Materials and methods:** We performed a retrospective, cross-sectional evaluation involving 85 patients diagnosed with postoperative lumbar spondylodiscitis between 2018 and 2024 at two tertiary care hospitals in Bucharest. Clinical data were retrospectively collected from patient records and included demographic variables, comorbidity profiles, discectomy level, latency from surgery to symptom onset, hospitalization duration, and Visual Analogue Scale (VAS) scores pre- and post-treatment. Comparative statistical analyses were conducted across clinically relevant subgroups, with a focus on comorbidity status. **Results:** Cardiovascular disease (CVD) and type II diabetes mellitus (DM) emerged as the predominant comorbidities. The lumbar region was the most frequently involved anatomical site, regardless of comorbidity presence. Patients with comorbidities were significantly older and exhibited extended hospital stays (Welch's t-test, $p < 0.05$). While comorbidity status did not significantly influence the mean time to symptom onset, complications such as fever and motor deficits were strongly associated with prolonged hospitalization. VAS scores improved substantially following treatment across all subgroups ($p < 0.05$); however, intergroup comparisons revealed no significant differences in pain reduction outcomes between patients with and without comorbidities. **Conclusions:** Pre-existing comorbidities are associated with a higher likelihood of postoperative lumbar spondylodiscitis and correlate with increased patient age and lengthier hospital stays. Nonetheless, the condition demonstrates a favorable response to treatment, particularly regarding pain reduction. These findings underscore the importance of early diagnosis and coordinated multidisciplinary care to improve clinical outcomes and mitigate long-term morbidity. **Keywords:** POSTOPERATIVE SPONDYLODISCITIS, LUMBAR DISC HERNIATION, SPINAL INFECTION, COMORBIDITIES, VAS SCORE, HOSPITALIZATION DURATION, PAIN MANAGEMENT.

"Spinal infections remain elusive in early stages, yet devastating when diagnosis is delayed." (Modic & Ross, "Infectious Discitis and Vertebral Osteomyelitis", Radiology, 1985)

INTRODUCTION

Infections of the lumbar spine following disc surgery presenting as discitis, vertebral osteomyelitis, or combined spondylodiscitis are uncommon but carry serious consequences. They occur in approximately 3-5% of lumbar interventions and primarily affect the lumbar region, with ~65% single-level, ~20% contiguous multilevel, and ~10% noncontiguous involvement (1, 2). These complications can lead to neurological deficits, spinal deformities, and segmental instability, making them clinically significant (1, 3, 4).

Postoperative spinal infections are driven by various patient and procedural risk factors. Comorbid conditions such as type II diabetes mellitus (DM), cardiovascular disease (CVD), obesity, immunosuppression, alcohol abuse, chronic steroid therapy, liver or kidney disease, prior spine operations, and malnutrition all increase susceptibility (4-6). In our cohort of 85 patients treated between 2018 and 2024, 81% had at least one major comorbidity with DM and CVD being the most prevalent mirroring trends seen in broader epidemiological studies (4, 5, 7).

Accurate diagnosis necessitates a comprehensive, multidisciplinary approach leveraging clinical signs, laboratory markers (ESR, CRP), advanced imaging (MRI, CT), and bacteriological cultures obtained from disc aspirates (7, 8). Staphylococcus aureus remains the most frequently isolated pathogen; however, culture-negative results can occur in up to 50% of cases, complicating treatment and increasing reliance on clinical judgment (8, 9).

Management strategies span from conservative treatments such as prolonged intravenous antibiotics and immobilization to early surgical intervention involving debridement and spinal stabilization. A meta-analysis of over 10,000 patients found that early surgery reduces mortality by ~39%, relapse by ~40%, and shortens hospital stays by about 7.8 days (8, 11).

Epidemiological studies indicate regional differences in incidence: less than 1% in Western countries, compared to 4-10% in India (9, 10). Moreover, rising incidence trends have been observed globally, particularly over the past two decades, attributed to aging populations and increased chronic disease prevalence (12-14). In our Bucharest-based cohort, higher postoperative infection rates were noted among elderly patients with significant comorbidities.

Given the substantial morbidity of postoperative lumbar spondylodiscitis, diagnostic uncertainty, and variable prognostic influence of comorbidities and complications, this study aims to enhance clinical understanding. Our retrospective cross-sectional analysis of 85 patients across two tertiary hospitals in Bucharest evaluates associations between patient comorbidities, latency to symptom onset, pre- and post-treatment VAS pain scores, occurrence of complications and hospitalization duration.

MATERIALS AND METHODS

This descriptive, cross-sectional study was conducted using secondary data extracted from general clinical observation records between 2018 and 2024 at two tertiary care centers in Bucharest: the Bucharest University Emergency Hospital and the Dr. Victor Babeș Clinical Hospital for Infectious and Tropical Diseases. The study was approved by the Ethics Committees of both institutions, and written informed consent for data processing and participa-

tion was obtained from each patient or their legal guardian.

The study is based on the hypothesis that certain patient-associated factors, such as pre-existing comorbidities, age, and neurological complications may significantly influence the clinical course of postoperative osteodiscitis and contribute to the risk of prolonged hospitalization or treatment failure.

Objectives. Primary Objective: to evaluate the association between comorbidities and the occurrence of complications in patients diagnosed with postoperative osteodiscitis.

Secondary Objectives: to assess demographic and clinical patterns associated with osteodiscitis severity and recovery outcomes; to compare pre- and post-treatment pain levels (VAS scores) across clinical subgroups; to analyze neurological deficits in relation to specific recovery patterns and to evaluate hospitalization duration based on comorbidities and complication status.

Study Population. The sample included 85 consecutively hospitalized patients diagnosed with postoperative osteodiscitis following lumbar disc herniation surgery, involving the thoracic, lumbar, or lumbosacral spine. Of these, 64 were treated at the Bucharest University Emergency Hospital and 21 at the Dr. Victor Babeș Clinical Hospital.

Data were extracted from clinical records and compiled into a structured database. Recorded variables included:

- Demographics (age, sex, residence, education level);
- Clinical factors (type and presence of comorbidities, presence of fever, neurological deficits, time to symptom onset);
- Surgical site (discectomy level);
- Pain intensity (VAS scores before and after treatment);
- Hospitalization duration.

Statistical Analysis. Patients were grouped for analysis based on sex, age, comorbidity status, complication status, and discectomy level. Statistical methods included:

- Independent samples t-test for comparing VAS scores and time to symptom onset between subgroups;
- Welch's t-test for mean age and hospitalization duration when variances were unequal;
- Chi-square (χ^2) test for assessing relationships between categorical variables (e.g., education level and residence);
- Shapiro-Wilk test for testing normality;
- Levene's test for homogeneity of variances;
- A p-value < 0.05 was considered statistically significant.

Results were synthesized into comparative tables and graphical visualizations.

Ethical Compliance. All research procedures adhered to the Declaration of Helsinki. The study received formal approval from both participating hospitals' Ethics Committees. Data confidentiality and patient privacy were strictly maintained throughout the study.

RESULTS

Among the total cohort of 85 patients diagnosed with postoperative lumbar spondylodiscitis, a significant proportion were admitted to the Bucharest University Emergency Hospital (n = 64), while the remaining cases were documented at the Dr. Victor Babeș Clinical Hospital for Infectious Diseases and Tropical Medicine (n = 21). The gender distribution showed a relatively balanced profile, with 43 female and 42 male patients enrolled across both institutions.

Notably, the University Emergency Hospital recorded 30 female patients and

34 male patients, whereas the Dr. Victor Babeș Hospital admitted 13 women and 8 men. This distribution illustrates a slight male predominance across the cohort but without a disproportionate representation between institutions (fig. 1).

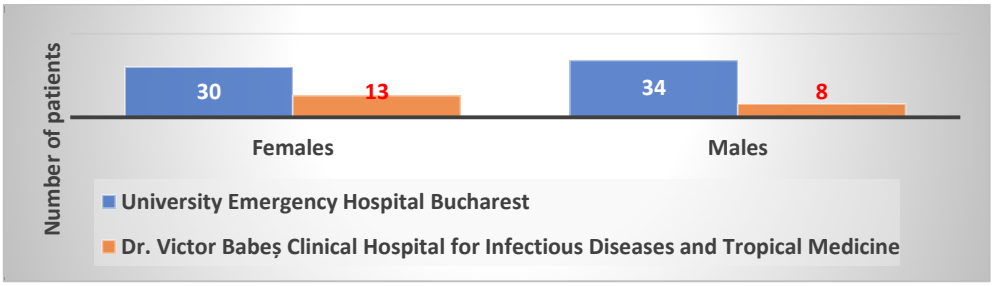

Fig. 1. Distribution of patients with postoperative osteodiscitis by sex and hospital of admission (University Emergency Hospital Bucharest - blue bars; Dr. Victor Babeș Clinical Hospital for Infectious Diseases and Tropical Medicine - orange bars)

An analysis of comorbidities within the study population revealed that cardiovascular diseases (CVD) were the most frequently encountered condition, affecting a total of 45 patients (26 women and 19 men). Type II diabetes mellitus (DM) represented the second most prevalent comorbidity, followed by cases of obesity, neoplasm, and other chronic conditions, which were relatively evenly distributed between sexes.

No statistically significant gender-based differences were observed in the distribution of any comorbidity category, as confirmed by the Chi-square test ($p > 0.05$), indicating a uniform comorbidity profile across male and female subgroups (fig. 2).

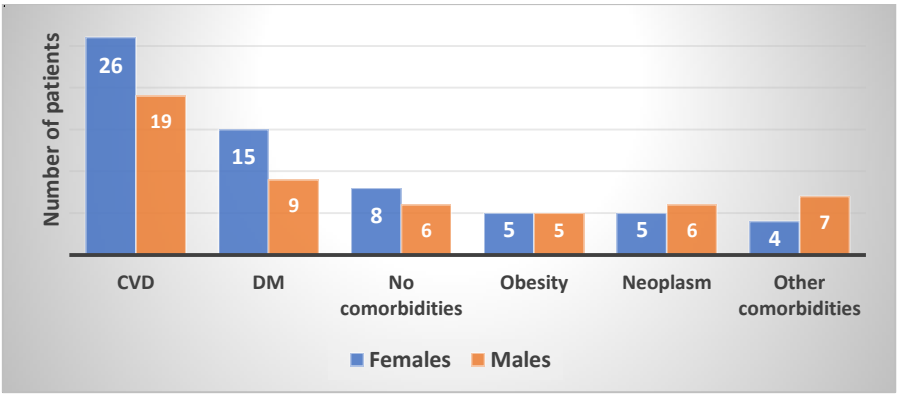

Fig. 2. Distribution of patients by comorbidities and gender.
(Blue bars = Females; Orange bars = Males.)

Among the 85 patients analyzed, a substantial majority - 69 individuals, accounting for 81.18%, had at least one documented comorbidity. As illustrated in Figure 3, cardiovascular diseases (CVD) were the most prevalent, affecting 45 patients, fol-

lowed by type II diabetes mellitus (DM), reported in 24 cases. Other notable comorbidities included oncologic conditions and various chronic pathologies grouped as "other", each present in 11 patients, while obesity was identified in 10 individuals.

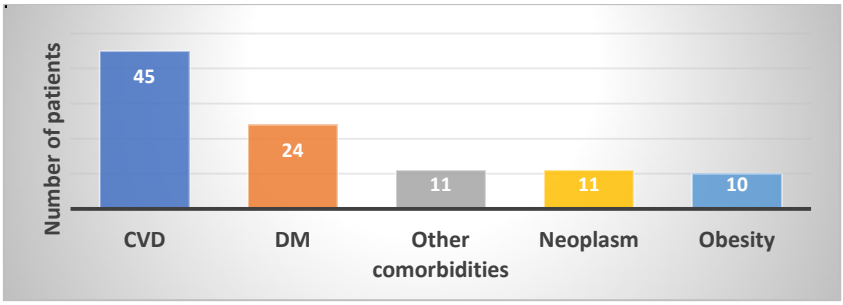

Fig. 3. Distribution of comorbidities among patients diagnosed with postoperative spondylodiscitis following lumbar disc herniation surgery.

The distribution presented in the first table reveals that the lumbar region was the most commonly affected site across all comorbidity categories, including in patients without any known comorbidities. For instance, among those with cardiovascular diseases, 33 out of 45 patients exhibited lumbar involvement, while 16 out of 24 diabetic patients showed similar localization. Thoracolumbar and lumbosacral levels were considerably less frequent.

Despite these observations, no statistically significant association was found between the presence of comorbidities and the level of osteodiscitis involvement. This was confirmed by both the Chi-square test and Fisher's exact test ($p \geq 0.05$ for both), indicating that comorbid status does not predict the anatomical level at which infection manifests.

Analysis of the second table highlights the variation for the mean time to symptom onset of postoperative osteodiscitis across different comorbidity groups. The longest average delay was observed in patients with obesity, who developed symptoms at approximately 12.9 weeks post-intervention (SD ±6.657). Conversely, the shortest interval was seen in patients with neoplastic conditions, with an onset average of 8.73 weeks (SD ±4.798).

Despite these numerical differences, none of the observed variations reached statistical significance when comparing presence versus absence of each comorbidity group (t-Student's test, $p \geq 0.05$ for all comparisons). The aggregated analysis of all comorbid patients *versus* those without comorbidities also revealed no significant difference in onset timing (mean 10.77 weeks *vs.* 9.19 weeks respectively).

Results showed a predominance of patients with comorbidities in the older age brackets, particularly between 60 and 79 years. The peak distribution of such cases was registered in the 60-64 age group, followed closely by the 70-74 cohort. In contrast, the number of patients without comorbidities was notably lower across all age categories, especially among those aged over 55 (fig. 4).

From a statistical standpoint, Levene's test indicated significant heterogeneity of variances between the two groups ($p < 0.05$), prompting the use of Welch's t-test, which confirmed that the mean age differed significantly between patients with

comorbidities and those without ($t(17.143) = 2.226$, $p < 0.05$). Though normality assumptions were not met (Shapiro-Wilk test, $p < 0.05$), the absence of extreme outliers (Z-score between -3 and +3) supports the reliability of this finding.

These observations underline the age-associated nature of comorbid conditions in the context of postoperative osteodiscitis, highlighting older individuals as a demographically vulnerable group in this cohort.

TABLE I.

Distribution of patients according to the presence of comorbidities and the level of discectomy

No.	Comorbidities	Discectomy level	Number of patients
1	Diabetes mellitus	Thoracolumbar	3
		Lumbar	16
		Lumbosacral	5
2	Cardiovascular diseases	Thoracolumbar	2
		Lumbar	33
		Lumbosacral	10
3	Obesity	Thoracolumbar	0
		Lumbar	9
		Lumbosacral	1
4	Neoplasm	Thoracolumbar	0
		Lumbar	9
		Lumbosacral	2
5	Other comorbidities	Thoracolumbar	1
		Lumbar	39
		Lumbosacral	12
6	No comorbidities	Thoracolumbar	1
		Lumbar	11
		Lumbosacral	0

TABLE II.

Distribution of patients according to the presence of comorbidities and the average time until onset of symptoms

No.	Comorbidities	Presence or absence	Median duration (weeks) until onset of symptoms	Number of patients
1	Diabetes mellitus	Yes	9.88 (SD±9.638)	24
		No	10.70 (SD±7.828)	61
2	CVD	Yes	10.84 (SD±9.436)	45
		No	10.05 (SD±6.969)	40
3	Obesity	Yes	12.90 (SD±6.657)	10
		No	10.15 (SD±8.510)	
4	Neoplasm	Yes	8.73 (SD±4.798)	11
		No	10.73 (SD±8.725)	74
5	Comorbidities (total)	Yes	10.77 (SD±7.901)	52
		No	9.19 (SD±8.451)	33

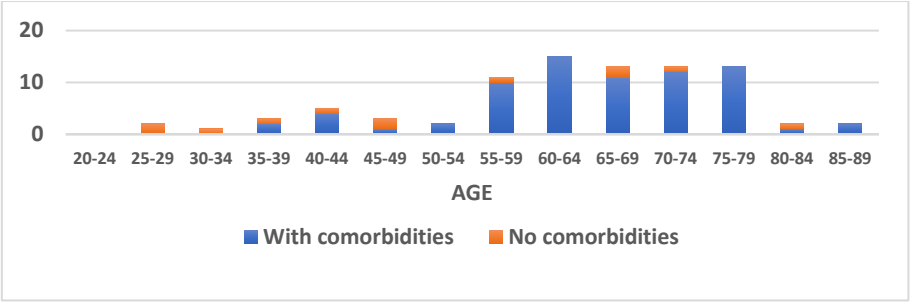

Fig. 4. Age group distribution of patients according to the presence or absence of comorbidities.

The preoperative VAS scores remain uniformly elevated across all categories, with minimal variance between patients with and without comorbidities, highlighting that baseline pain perception was not significantly influenced by comorbid status (fig. 5). This aligns with prior literature suggesting that the initial severity of symptoms in spondylodiscitis may be more a function of disease localization than of systemic factors (Modic & Ross, 1985).

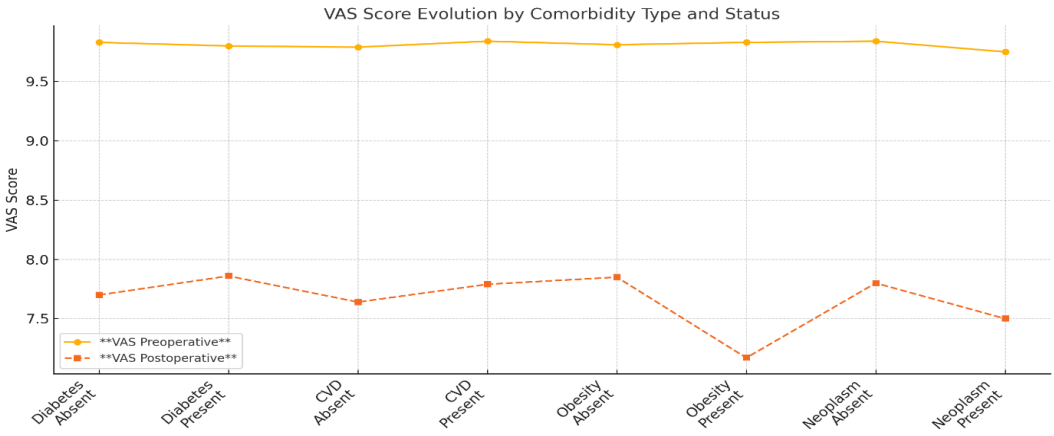

Fig. 5. Evolution of VAS scores by comorbidity type and status.

A marked reduction in VAS scores across all spinal levels following treatment is represented in figure 6, with the thoracolumbar subgroup showing the most pronounced improvement suggesting that anatomical site may influence analgesic response, independent of baseline symptom severity.

According to Welch's t-test, patients with pre-existing comorbidities experienced substantially longer hospital stays (mean = 16.46 days) than those without (mean = 3.75 days), a difference that remained statistically significant despite variance heterogeneity (Levene's test, $p < 0.05$; Welch's test, $p < 0.05$). This aligns with prior observations that systemic disease burden prolongs recovery time and complicates discharge planning.

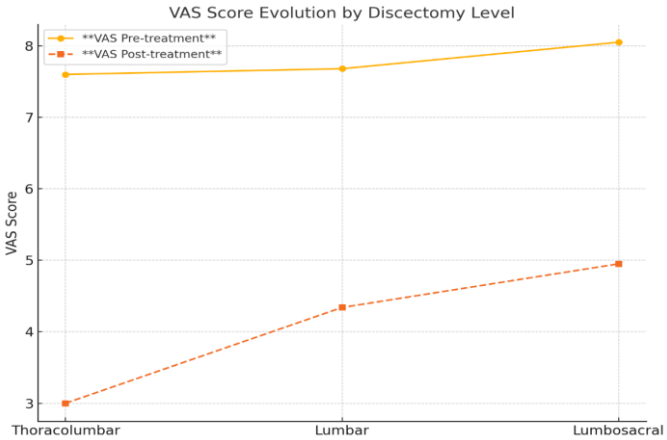

Fig. 6. Evolution of VAS scores before and after treatment, by discectomy level.

Similarly, the presence of postoperative complications-most notably infectious or wound-related-was associated with prolonged inpatient care (23.25 *vs.* 10.35 days; $p < 0.05$), even though Levene's test confirmed equal variances. Interestingly, fever did not influence the average length of stay ($p \geq 0.05$), possibly due to the limited number of febrile patients (n = 3) and overlapping management strategies in afebrile cases with other complications.

Notably, the analysis also identified a counterintuitive trend regarding motor deficits: patients with neurological impairment had shorter hospitalizations on average (8.83 *vs.* 22.67 days), a result that was statistically significant (Welch's test, $p < 0.05$) but potentially influenced by early discharge for rehabilitation or social factors (fig. 7).

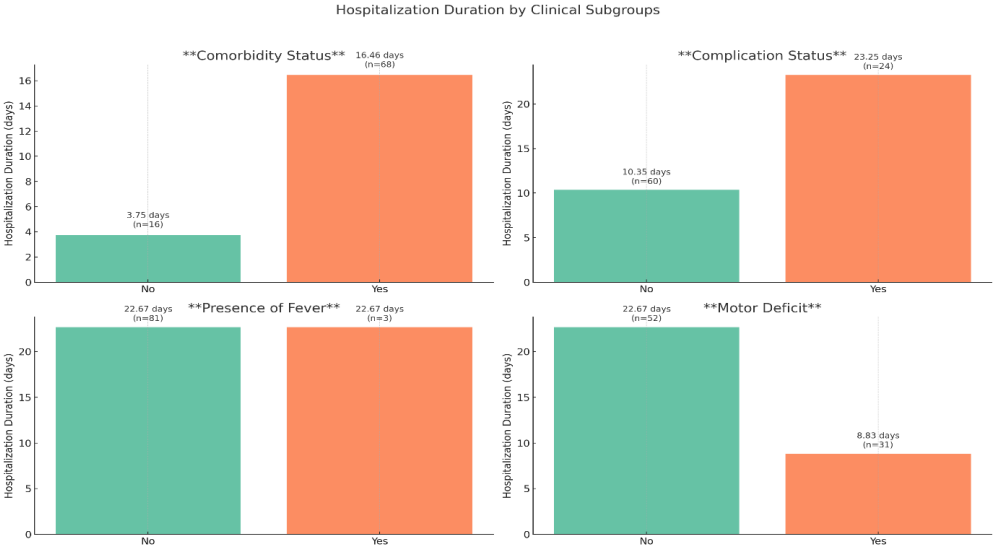

Fig. 7. Hospitalization duration by presence of comorbidities, complications, fever, and motor deficit

DISCUSSION

Multiple studies have confirmed that the presence of preoperative comorbidities, particularly diabetes and cardiovascular disease, correlates with extended hospitalization, increased complication rates, and delayed recovery (15). Our results support this, with statistically significant differences observed in length of stay between patients with and without comorbidities. Similar patterns have been described in a multicenter prospective analysis involving 102 patients, where comorbid individuals had a mean hospitalization duration 1.8 times longer than those without (16).

The relationship between infectious complications and hospitalization is particularly critical in the setting of spinal surgery. A recent cohort study emphasized that even minor postoperative infections can double the duration of hospital stay, particularly in immunocompromised populations (17). This finding resonates with our data, where patients experiencing complications such as fever or local infection exhibited an average hospital stay exceeding three weeks.

Regarding motor deficits, our findings revealed a paradoxical trend-patients with neurological impairment were discharged earlier than those without. Although initially counterintuitive, this pattern has been reported in prior literature and is hypothesized to result from early rehabilitation transfers or limited surgical benefit in advanced neurological decline (18). These cases often follow distinct clinical pathways not entirely captured by general length-of-stay metrics.

Pain relief, as assessed by the VAS score, demonstrated significant improvement post-treatment across all subgroups, regardless of sex or comorbidity profile. This is consistent with a recent retrospective series involving 89 patients, where over 85% experienced a clinically meaningful reduction in pain within the first 4 weeks following antibiotic and/or surgical intervention (19). Importantly, our results show that anatomical localization-particularly thoracolumbar involvement-is associated with superior analgesic outcomes, a finding also observed by Kim *et al*. in their comparison of thoracic versus lumbar infections (20).

There remains ongoing debate regarding the role of early surgical intervention in spondylodiscitis. Our dataset supports the notion that early, targeted debridement and stabilization can facilitate pain reduction and reduce relapse risk, consistent with contemporary meta-analytical evidence (21).

CONCLUSIONS

This retrospective cross-sectional study provides robust evidence on the clinical course, pain outcomes, and hospitalization burden associated with postoperative lumbar spondylodiscitis in a Romanian tertiary care context. Our cohort of 85 patients revealed key associations that may inform future diagnostic and management pathways for this complex condition.

One of the most significant findings relates to the evolution of pain intensity, quantified using the Visual Analogue Scale (VAS). Across the entire study population, the mean VAS score decreased from 7.76 pre-treatment to 4.40 post-treatment, a statistically significant improvement ($p < 0.05$, paired t-test). This analgesic benefit was consistently observed across all sub-

groups, regardless of sex, comorbidity presence, or discectomy level. Notably, patients with thoracolumbar discectomy experienced the most pronounced improvement, with a mean post-treatment VAS of 3.0, compared to 4.34 for lumbar and 4.95 for lumbosacral involvement. This anatomic variance reached statistical significance ($p < 0.05$), suggesting that spinal level may influence therapeutic responsiveness.

Equally important were the insights into hospitalization duration. Statistical comparisons revealed that patients with comorbidities had a mean hospital stay of 16.46 days, significantly longer than those without comorbidities (3.75 days; Welch's t-test, $p < 0.05$). Levene's test confirmed unequal variances ($p < 0.05$), validating the use of Welch correction. Additionally, the presence of postoperative complications was associated with markedly extended hospitalization (23.25 *vs.* 10.35 days; $p < 0.05$), despite homogeneity of variance. These findings reinforce the critical role that systemic health and postoperative course play in determining resource utilization and clinical recovery.

Interestingly, motor deficits often considered markers of severe disease, were paradoxically associated with shorter hospitalizations (8.83 *vs.* 22.67 days; Welch's test, $p < 0.05$).

This result may reflect early discharge for rehabilitation or divergent clinical pathways, underscoring the need for cautious interpretation.

Although sex and specific comorbidities (e.g., diabetes, cardiovascular disease) did not significantly influence the degree of pain relief, their presence clearly impacted hospitalization metrics. These results emphasize the importance of early identification of high-risk patients, as well as the need for coordinated care plans that account for both infectious and non-infectious drivers of morbidity.

This study confirms that while postoperative lumbar spondylodiscitis responds favorably to targeted treatment in terms of pain relief, its clinical trajectory is heavily modulated by the presence of comorbidities and surgical complications.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interests, and they received no specific funding regarding this scientific research.

MEDICATION AND REGULATION OF ACUTE POSTOPERATORY PAIN, USING MULTIMODAL THERAPY (Abstract): Surgical interventions and opioid exposure activate both peripheral (satellite glial cells) and central glia (microglia and astrocytes), contributing to peripheral and central sensitization and maintenance of pain. Specific molecules such as MMP-9 and IL-1β are involved. **Materials and methods**: We analyzed female patients who presented for emergency or elective abdominal surgery at the "Cuza-Voda" Hospital of Obstetrics and Gynecology Iași, Romania and who met the following inclusion criteria and did not present any of the exclusion criteria were included in the analysis. Inclusion criteria: Age over 18 years; Surgical obstetrical or gynecological indication. exclusion criteria: patients under 18 years of age; people with suspected sepsis or serious medical comorbidities such as heart failure, undiagnosed fever and instable state. The study was retrospective and prospective, during January 2024 to November 2025, starting from the clinical parameters, surgery indication, analyzing clinically and paraclinically, the importance of intra- and postoperative analgesic medication that was used. **Results:** Of the total study group, 52.3% of patients underwent cesarean sections (CST), 14.4% underwent total hysterectomy with bilateral adnexectomy (HT+AB) and 9% underwent biopsy curettage, the rest of gynecological surgeries consisted of Madden mastectomy, salpingectomy, ovarian cyst removal. Multimodal drug therapy and opioid treatments were required to achieve the control of post operatory pain. **Conclusions**: Current areas of interest in pain research include investigating the effect of mood on pain processing in the brain and the search for new drugs to block the channels involved in pain transmission, and the actual important post operatory pain therapy involves a combination of multimodal and opioid treatments. **Keywords***:* PAIN, RECEPTOR, POLYMORPHISM, OPIOID THERAPY, MULTIMODAL TREATMENT.

INTRODUCTION

Pain is one of the most subject symptoms concerning patient care in healthcare. Primary afferent fibers, Aδ and C fibers that carry noxious sensory information, are extra primary Aβ fibers that carry non-noxious stimuli (1). Each of these fiber types has different characteristics that allow the transmission of certain types of sensory information (2). Aβ fibers are heavily myelinated and of large diameter, thus allowing rapid signal conduction. They have a low activation threshold and usually respond to light touch and transmit innocuous stimuli. Aδ fibers are lightly myelinated and of smaller diameter and, therefore, conduct more slowly than Aβ fibers. They respond to mechanical and thermal stimuli. They interpret fast, sharp pain and are responsible for the initial re-

flex response to acute pain (3). C fibers are unmyelinated and are also the smallest type of primary afferent fiber. Therefore, they demonstrate slow conduction. C fibers are polymodal, responding to chemical, mechanical, and thermal stimuli. C fiber activation results in slow, burning pain. These reactions have been studied in orofacial surgery, neurological diseases, and general surgery (4, 5).

Peripheral sensitization is a state of hypersensitivity and hyperexcitability of nociceptors, caused by inflammation and injury. It involves activation of a variety of ion channels and protein kinases (6). Central sensitization: Persistent nociceptive stimulation leads to changes in the central nervous system, involving increased excitability of neurons in the spinal cord and brain. This contributes to chronic pain (7, 8, 9). Glial activation and neuroinflammation after surgery/opioid treatment: Surgical interventions and opioid exposure activate both peripheral (satellite glial cells) and central glia (microglia and astrocytes), contributing to peripheral and central sensitization and maintenance of pain. Specific molecules such as MMP-9 and IL-1β are involved and more research is required to understand this process (10, 11, 12).

MATERIALS AND METHODS

Study perspective. We analyzed 111 female patients who presented for emergency or elective abdominal surgery at the "Cuza-Voda" Hospital of Obstetrics and Gynecology Iași, Romania and who met the following inclusion criteria and did not present any of the exclusion criteria.

The study was retrospective and prospective, during December 2024 to December 2025, starting from the clinical parameters, surgery indication, analyzing clinically and paraclinically, the importance of intra- and post-operative analgesic medication that was used.

Inclusion criteria were formed by: age above 18 years; associated obstetrical or gynecological surgical intervention.

Exclusion criteria were patients under 18 years of age; persons with suspected sepsis or associated severe medical pathologies

The general objective was evaluating the effectiveness of the treatment of moderate to severe postoperative pain in patients who present major risk factors for having an unusually high level of acute postoperative pain.

Statistical analysis. Descriptive and analytical methods were used in the statistical analysis. After collecting the data, in an accessible form to ensure their informational character, their processing was carried out. The data were centralized in *Excel* and *SPSS* databases and processed with the statistical functions to which they lend themselves. In the presentation of the data, confidence intervals at the 95% significance threshold were used, and the χ^2 and t-Student tests were used to test the differences. The normality testing of quantitative value series was performed with the Kolmogorov-Smirnov test used to test large data sets. The threshold chosen in testing the null hypothesis is $p > 0.05$, therefore the variables are normally distributed. Normality tests Skewness or Kurtosis, which often involve skewness, assess whether the distribution of a data set resembles a normal distribution. Skewness measures the skewness of the Linear regression, by the method of least squares, was the modeling method used. It is the method called "regression", "linear regression", "multiple regression" or "least squares" when building a model.

RESULTS

Particularities of the drug treatment used before hospitalization

Before the surgical intervention, 8.6% of the patients with cesarean section (CSS) received Aspenter 75 mg, 100 mg, respectively 150 mg and 15.5% other medication such as Euthyrox for thyroid pathology, Metformin for diabetes pathology, while patients with interventions such as total hysterectomy with bilateral adnexectomy (HT+AB) did not receive medication before the surgical intervention ($p = 0.002$).

Type of surgery performed and surgical outcomes

Of the total study group, 52.3% of patients underwent cesarean sections (CST), 14.4% underwent total hysterectomy with bilateral adnexectomy (HT+AB) and 9% underwent biopsy curettage, the rest of gynecological surgeries consisted of Madden mastectomy, salpingectomy, ovarian cyst removal.

Cesarean section results (CST). Of the 58 patients with cesarean section, 79.3% were under 36 years of age, while 83% of patients with other types of surgery were over 36 years of age ($p = 0.001$).

In patients with cesarean section, the series of values for gestation, number of weeks of pregnancy, birth weight, Apgar and number of days of hospitalization are distributed with the values of the Kurtosis test > 2 and the values of the Kolmogorov-Smirnov test < 0.05, while the series of values for parity varies in the range 1-4; group mean 1.72 ± 0.76; median 2; Kurtosis test result 1.249 and $p > 0.05$ in Kolmogorov-Smirnov test, which suggests that statistical significance tests can be applied for continuous variables.

Before surgery, 8.6% of patients with cesarean section received aspirin and 15.5% other medication, while patients with HT+AB did not receive medication before surgery ($p = 0.002$).

Demographic features of analyzed patients according to the medication

Of the 17 patients treated intraoperatively with Mialgin, 88.2% were over 36 years old ($p=0.001$) and 64.7% came from urban areas ($p=0.424$). Of the 30 patients treated intraoperatively with Fentanyl, 73.3% were over 36 years old ($p = 0.003$) and 76.7% came from urban areas ($p = 0.219$). Of the 12 patients treated intraoperatively with Diazepam, all were under 36 years old ($p = 0.001$) and 66.7% came from urban areas ($p = 0.532$). The only patient treated intraoperatively with Phenobarbital was under 36 years old and came from rural areas, and the patient treated with Morphine was over 36 years old and came from rural areas.

Associated pathologies and the association with the medication

Of the 17 patients treated intraoperatively with Mialgin, 35.3% had iron deficiency anemia ($p = 0.494$), 29.4% adhesion syndrome ($p = 0.053$) and 17.6% uterine fibroids ($p = 0.071$). Of the 30 patients treated intraoperatively with Fentanyl, 36.7% had iron deficiency anemia ($p = 0.359$), 26.7% postoperative adhesion syndrome ($p = 0.019$), 10% hereditary thrombophilia ($p = 0.283$), 6.7% had hypertension ($p = 0.177$) and 3.3% diabetes mellitus ($p = 0.705$). Of the 12 patients treated intraoperatively with Diazepam, 25% had uterine fibroids ($p = 0.027$), 16.7% iron deficiency anemia ($p=0.184$), 16.7% adhesion syndrome ($p = 0.506$) and 8.3% had hereditary thrombophilia ($p = 0.562$).

Hospitalization period, according to OG surgical interventions performed

Treatment with analgesics, depending on the surgical intervention, highlights the following aspects (fig. 1):

- 8.6% patients with cesarean section (CST), were treated intraoperatively with Fentanyl (p = 0.001);
- 62.5% of patients with total hysterectomy with bilateral adnexectomy (HT+AB) were treated intraoperatively with Fentanyl (p=0.001);
- 40% patients with classical or laparoscopic unilateral ovarian cystectomy were treated intraoperatively with Fentanyl and 20% with Diazepam (p=0.001);
- 33.3% of patients with interventional hysteroscopy were treated intraoperatively with Mialgin and 33.3% with Fentanyl (p = 0.001);
- among patients with classical or laparoscopic uterine myomectomy, 50% were treated intraoperatively with Mialgin, 50% with Fentanyl and 50% with Diazepam (p = 0.001);
- among patients with Madden-type radical mastectomy, 50% were treated intraoperatively with Mialgin, all patients with Fentanyl and 50% with Diazepam (p = 0.001).

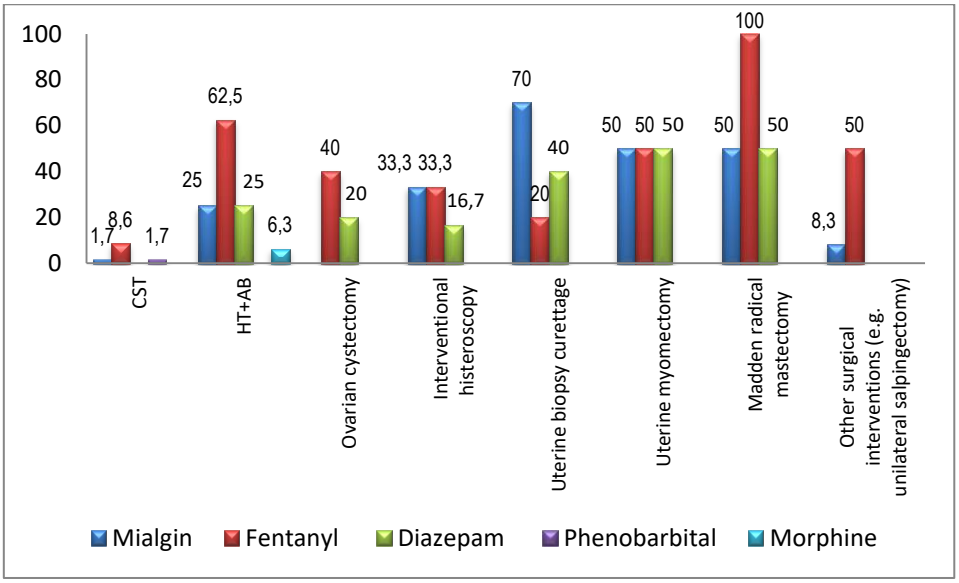

Fig. 1. Correlation of medication with type of surgical intervention

Intraoperative drug treatment

Ibuprofen, dosage 400 mg injectable solution / 100 mL was administered intraoperatively in 1 to 3 doses to 25.9% of patients with CST and 17% of those with other types (p=0.258) .80% of the patients with CST, 33.3% of those with ovarian cystectomy and all with HT+AB received a single dose of Ibuprofen (p=0.329). Paracetamol, 10 mg/mL 100 mL was administered intraoperatively in 1-4 doses to 89.7% of the patients with CST and 79.3% of those with other types (p = 0.130). A total of 51.9% of the patients with CST, 66.7% of those with hysteroscopy or biopsy uterine curettage received a single dose of Parace-

tamol, while 38.5% of the patients with CST, 50% of those with myomectomy or mastectomy received two doses of Paracetamol. Three doses were received by 53.3% of patients with HT+AB, 50% of those with myomectomy or mastectomy and all with ovarian cystectomy (p=0.001).

Mabron, dosage 50 mg/mL 2 mL was administered intraoperatively in 1-3 doses to 93.1% of patients with CST and 49.1% of those with other types (p = 0.001). 70.9% of patients with CST and all with mastectomy received a single dose of Mabron. Two doses were received by all with ovarian cystectomy, 61.5% of patients with HT+AB, 50% of those with myomectomy, 27.5% of patients with CST (p = 0.004).

Algocamin, dosage 1 g/2 mL was administered intraoperatively in 1-4 doses to 89.7% of patients with CST and 64.2% of those with other types (p = 0.001). For 51.9% of patients with CST, 50% with ovarian cystectomy or myomectomy, 33.3% with hysteroscopy or biopsy curettage they received a single dose of Algocamin. All patients with mastectomy, 66.7% of patients with biopsy curettage, 50% of those with HT+AB, 44.2% of patients with CST received two doses (p = 0.041). Only 14.3% of patients with HT+AB received four doses.

Acupan, dosage 20 mg/2 mL was administered intraoperatively in 1-3 doses to 65.5% of patients with CST and 37.7% of those with other types (p=0.004). 86.8% of patients with CST, all with hysteroscopy, biopsy curettage, myomectomy, or mastectomy received a single dose of Acupan. All patients with ovarian cystectomy received two doses, 50% of patients with HT+AB, 13.2% of patients with CST (p = 0.049). Only 12.5% of patients with HT+AB received three doses.

Refen, dosage 25 mg/3 mL was administered intraoperatively in 1-4 doses to 82.8% of patients with CST and 73.6% of those with other types (p = 0.243). 83.8% of patients with uterine biopsy curettage, 72.9% of patients with CST, 66.7% with hysteroscopy and 15.4% with HT+AB received a single dose of Refen. All patients with ovarian cystectomy or mastectomy, 50% of patients with myomectomy, 30.8% of those with HT+AB and 25% of patients with CST received two doses (p = 0.005). Four doses were received by only 7.7% of the patients with HT+AB.

Postoperative drug treatment

Postoperative treatment with Clexane was received by 76.6% of the patients in the present study group, all patients with myomectomy, 93.1% of the patients with CST, 81.3% of the patients with HT+AB, 60% with ovarian cystectomy, 50% with mastectomy, 33.3% with hysteroscopy and 30% with biopsy curettage (p = 0.001).

Postoperative treatment with Cefotax was received by 17.1% of the patients in the present study group, including all patients with myomectomy, 50% of the patients with HT+AB, 40% with ovarian cystectomy and 33.3% with hysteroscopy (p = 0.001). Refen, 25 mg/3 mL was administered postoperatively in 1-22 doses to 82.8% of patients with CST and 60.4% of those with other types (p = 0.004). 50% of patients with myomectomy, 33.3% of patients with biopsy curettage, Algocamin, dosage 1 g/2 mL was administered postoperatively in 1-16 doses to 74.1% of patients with CST and 52.8% of those with other types (p=0.020). 50% of patients with mastectomy, 33.3% of patients with HT+AB and 20.5% of those with CST received postoperatively 1-2 doses of Algocamin. All patients with myomectomy, 58.2% of patients with CST, 33.3% of patients with

ovarian cystectomy and 8.3% of those with HT+AB received 3-5 doses of Algocamin postoperatively. More than 5 doses of Algocamin were received by all patients with hysteroscopy, 66.7% of patients with ovarian cystectomy, 58.4% with HT+AB, 50% of those with mastectomy and 20.5% of patients with CST ($p = 0.005$). The morphine receptor mutation (OPRM1) was more frequently present in patients with biopsy curettage (60%), myomectomy (50%), mastectomy (50%), hysteroscopy (33.3%), CST (20.7%) and ovarian cystectomy (20%) ($p = 0.048$). There were no statistically significant differences by age group ($p = 0.785$).

DISCUSSION

Cesarean rates in Romania are increasing at a total of 60% of births. Our results show that caesarean sections were performed in 79.3% of cases in patients younger than 36 years of age. Pain management with opioids and anxiolytics during and after this type of surgery was managed with Mialgin in 17 patients, Diazepam in 12 patients, Fentanyl in 8.6% of cases.

Opioids bind to and stimulate opioid receptors (mu, kappa, and delta) that are found in the brain, spinal cord, peripheral nervous system, and gastrointestinal tract. Opioid receptors are a type of G protein-coupled receptor and are found in the central and peripheral nervous systems and are involved in many aspects of nervous system function, including sympathetic and parasympathetic activity and pain modulation. (18, 19). Because exogenous opioids, such as morphine and fentanyl, perform the same action as enkephalins at the receptor level, they can have an effect anywhere, especially in the midbrain, pons, medulla, and spinal cord (7).

In terms of pain modulation, studies describe that some signals from the sensory cortex or from afferent fibers travel along the spinothalamic tract ending in the periaqueductal gray area of the midbrain. Endogenous opioids are released, enkephalins, which stimulate neurons with fibers that transmit information to the locus coeruleus within the brainstem pons and the locus raphe magnus in the medulla. (10, 21). Our study followed the usage of dexamethasone as a co-administration during the induction phase of the regional analgesia, before blockage pain installment, because it can reduce pain by blocking the intracellular conversion of phospholipids to arachidonic acid, and our study found it beneficial for pain management (16, 17).

In our study intraoperative drug treatments consisted of 1-3 doses of Ibuprofen in 25.9% of caesarean surgeries, 33.3% of ovarian cystectomies and at least one dose in all cases of hysterectomies. More than half of patients received a dose of Paracetamol, while larger surgeries such as mastectomies and myomectomies received 2 doses. Analgesics, such as, non-steroid anti-inflammatory pills (NSAIDs), as ibuprofen, block the synthesis of all prostaglandins, including PGI2 (prostacyclin), thereby slowing or stopping inflammation (13). The inflammatory process and pain reduction occur by blocking the formation of PGE2. This is achieved by blocking COX-1 and COX-2. COX-1 is found in low concentrations in a balanced proportion throughout the body, and COX-2 is the inducible form, which is dramatically increased during inflammatory states, such as immediate post operatory phase (14, 15).

Mabron, tramadol, an opioid analgesic, that relieves pain by acting on specific nerve cells in the spinal cord and brain was administered in 93% of caesarean surgeries

and in 49.1% of total surgeries described.

Algocalmin an analgesic and antipyretic with indications that include severe post-injury or postoperative pain, was prescribed in up to 4 doses in 89.7% of caesarean surgeries and more than half of all other surgeries.

Acupan, an analgesic symptomatic treatment of short-term painful conditions, in particular post-operative pain was administered in 65.5% of caesarean sections and 37.7% of all other surgeries, during the intraoperative period and did not require multiple doses except for 15% of total hysterectomies.

Refen is a non-steroidal anti inflammatory drug that has the active substance diclofenac sodium. Refen is presented as an injection/infusion solution and is used to treat acute pain.

Our study described its utility in more than 72% of caesarean sections, half of uterine gynecological surgeries, with up to 4 doses in 7.7% of cases during the intraoperative period.

Multimodal pain management offers a comprehensive strategy to improve function and quality of life while minimizing opioid use. Increasing access to interventional pain techniques through collaboration between surgeon and anesthesiologist can make an important difference between poorly controlled pain and a stable, comfortable postoperative patient.

Minimizing pain enhances long and short - term quality of life, reduces complications in the immediate and late postoperative phase and increases confidence in the surgical act and in the postoperative recovery time.

CONCLUSIONS

Multimodal analgesia is used to characterize the use of combinations of drugs with different modes of action. In this way, it is possible to use lower doses of drugs, thus minimizing unwanted side effects.

By using a combination of NSAIDs and opioids for postoperative pain, the amount of opioid required is much lower and opioid-related side effects become less significant. Pain is both a sensory and emotional experience, and patients' previous experiences, fears and anxieties can play an important role. Pain transmission is the result of complex peripheral and central processes. These processes can be modulated at different levels, and pain perception is the result of the balance between facilitatory and inhibitory interactions.

Current areas of interest in pain research include investigating the effect of mood on pain processing in the brain and the search for new drugs to block the channels involved in pain transmission.

Thus, in the pathophysiology of pain it is important to understand that: the pain experienced by patients is the result of the interaction between sensory and emotional experiences. Aδ fibers transmit fast, sharp, localized pain. 3 C fibers transmit slow, diffuse, dull pain.

Pain transmission can be modulated at several levels, including the dorsal horn of the spinal cord and by descending inhibitory pathways. The spinothalamic and spinoreticular tracts are important ascending pain transmission pathways. Neuropathic pain can be spontaneous and is often described as a burning sensation or can be felt very strongly by the patient.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

INDEPENDENT PREDICTORS OF RESILIENCE IN OLDER ADULTS: INSIGHTS FROM A PROSPECTIVE CLINICAL STUDY (Abstract): **Aims:** To evaluate the four types of resilience (physical, mental, emotional, and social) and their associations with functional capacity, physical performance, nutritional and cognitive status, muscle strength, and depressive symptoms in older adults. **Materials and methods:** This prospective study included 110 patients aged ≥ 50 years admitted to Dr. C.I. Parhon Clinical Hospital, Iași, with acute conditions or acute exacerbations of chronic diseases who underwent comprehensive geriatric assessment and were evaluated with the Physical Resilience Scale. Data were analyzed using nonparametric tests, Spearman correlations, and univariate/multivariate generalized linear models; significance was set at $p<0.05$. **Results:** Median resilience was 10 (IQR 8–13). Resilience showed significant positive correlations with ADL (R=0.218), IADL (R=0.397), SPPB (R=0.458), MNA (R=0.377), MMSE (R=0.322), and upper-limb muscle strength (R≈0.33). Negative correlations were observed with GDS (R=-0.676), Fried phenotype (R=-0.462), and fall risk (R=-0.331). Multivariable analysis identified IADL (IRR=1.032, p=0.043) and GDS (IRR=0.947, $p<0.001$) as independent predictors of resilience. Resilience did not differ according to heart failure, urinary tract infection, or osteoarticular disease, but was significantly lower in patients with reduced muscle strength. **Conclusions:** Resilience in older adults is a multidimensional construct closely associated with functional independence and mental health. IADL and depressive symptoms are independent determinants of resilience, underscoring the importance of maintaining autonomy and addressing depression. Multidomain interventions targeting these factors may enhance resilience and reduce vulnerability to adverse outcomes in aging populations. Longitudinal studies are warranted to clarify causal relationships and evaluate the efficacy of resilience-promoting strategies. **Keywords**: RESILIENCE, INTRINSIC CAPACITY, OLD PATIENTS, FRAILTY, RECOVERY.

INTRODUCTION

Aging is accompanied by a progressive loss of physiological reserves and an increased vulnerability to disease, functional decline, and disability, which needs a shift from a care model focused exclusively on disease to one oriented toward preserving functional capacity and quality of life in older adults (1). In this context, the concepts of resilience (particularly physical resilience) and intrinsic capacity (IC) have emerged as complementary frameworks

that can guide proactive interventions for "successful aging" (2,3). Resilience is defined as a multidimensional dynamic process that enables a person to withstand, adapt to, and recover from acute or chronic stressors. Resilience has four major components: physical, mental, emotional, and social resilience. Physical resilience specifically reflects the ability to avoid or recover from functional decline following an acute adverse health event. Psychological resilience reflects the capacity to maintain or regain stable mental health and to adapt well in the face of adversity, and to sustain functioning without long-term psychological disruption. Emotional resilience is the ability to recognize, manage, and recover from emotional stressors and and to regulate emotional responses effectively. Social resilience stems from social connection and involves teamwork, network-building, and community engagement (4). Intrinsic capacity, promoted by the World Health Organization through the ICOPE framework, brings together an individual's mental and physical reserves across five interconnected domains: locomotor, vitality, cognitive, sensory, and psychological; the composite IC score is a strong predictor of progression toward frailty, functional decline, and mortality (5, 6).

The Comprehensive Geriatric Assessment (CGA) integrates the measurement of geriatric functions and syndromes and gains additional prognostic and interventional value when it also includes the assessment of resilience and IC. Recent data show that implementing the CGA reduces unplanned hospitalizations, institutionalization, and deterioration in the ability to perform activities of daily living (8, 9). In practice, the short, validated instruments frequently used in geriatric assessment: activities of daily living (ADL), instrumental activities of daily living (IADL), Mini - Mental State Examination (MMSE), Geriatric Depression Scale (GDS), Mini Nutritional Assessment (MNA), Short Physical Performance Battery (SPPB), handgrip strength test, and fall risk scores (e.g., the Downton Scale), and the Fried frailty phenotype correspond, in most studies, to the IC domains and physiological components of resilience and have predictive value for clinical outcomes (falls, functional decline, hospitalization, mortality)(10, 11, 12). For example, the SPPB and walking speed are recognized as strong predictors of disability and morbidity, and the "vitality" domain (MNA, grip strength) frequently emerges as a major determinant of physical resilience and frailty risk (13, 14). The Physical Resilience Scale (PRS), validated in studies of older adults (e.g., Resnick *et al.*), provides a specific measure of post-stressor recovery capacity through self-reported assessment of reactions to health events, complementing functional tests and providing prognostic information regarding the trajectory of recovery and the need for rehabilitation interventions (15, 16).

Recent literature highlights the interdependence between IC and resilience: IC represents the necessary baseline reserves, while resilience reflects the dynamic mobilization of these reserves in the face of stressors; thus, interventions that enhance key domains of CI (e.g., multicomponent exercise programs, nutritional optimization, psychosocial support) also enhance resilience and reduce the risk of progression toward frailty and disability (17, 18, 19). Recent meta-analyses and randomized trials show that multidomain interventions (exercise + nutrition + cognitive stimulation) improve functional performance,

cognitive and psych affective status, and reduce the prevalence of frailty and loss of independence over follow-up periods (20, 21). Consequently, the systematic inclusion of measures such as ADL/IADL, MMSE, GDS, MNA, SPPB, the Downton scale, and the Fried phenotype assessment in geriatric patients not only provides a useful functional description but can also guide targeted interventions to increase physiological reserve and recovery capacity in older adults (22, 23).

Standard CGA assessments remain essential, as they correlate with relevant components of resilience: locomotor and nutritional reserve, cognitive status, and psychological status, all of which determine recovery potential. However, resilience, as assessed by the physical resilience scale, complements these static measures by highlighting the speed and trajectory of recovery, key indicators for therapeutic decisions and rehabilitation planning (2, 22).

MATERIALS AND METHODS

This prospective study was initiated in March 2025, and presents preliminary data collected between March - September 2025 on 110 patients aged > 50 years admitted to the Dr. C.I. Parhon Clinical Hospital in Iași for acute medical events such as acute decompensated heart failure, urinary sepsis, and functional decompensation of chronic osteoarticular diseases. The exclusion criteria were as follows: age under 50 years, lack of informed consent, inability to obtain clinical and biochemical data, impaired cognitive status with an MMSE < 15, and inability to apply the resilience assessment scale. The study was approved by the Ethics Committee of the hospital and by the Ethics Committee of the Grigore T. Popa University of Medicine and Pharmacy, Iasi (Registration No: 8357/17.09.2024; 490/ 02.11.2024).

All patients included in the study underwent an assessment of intrinsic capacity using the following scales: MMSE, MNA, GDS, functional status - ADL, IADL, SPPB, fall risk- Downton scale, and the Frailty Phenotype by Freid (24). At the same time, we measured muscle strength in both upper limbs using a dynamometer, assessed pain using a visual analog scale, and collected data on the presence of heart failure. Additionally, to assess resilience, we applied the Physical Resilience Scale (16). Muscle strength was assessed using a dynamometer, and the values were interpreted according to sex and age, with specific thresholds for men and women, defining normal, low, or high values. For men aged 65 to 69, normal muscle strength ranged from 28.2 kg to 44.0 kg, and for those aged 70 to 99, from 21.3 kg to 35.1 kg. For women aged 65 to 69, normal muscle strength ranged from 15.4 kg to 27.2 kg, and for those aged 70 to 99, from 14.7 kg to 24.5 kg. Values below the lower limit were considered low, and those above the upper limit were considered high (25). Cognitive status was assessed using the MMSE scale (0–30 points), with normal cognitive function ranging from 25 to 30, mild impairment from 20 to 24, moderate impairment from 10 to 19, and severe impairment below 10 points (26). Nutritional assessment was based on the MNA questionnaire (24-30 indicates normal nutrition, 17-23.5 indicates a risk of malnutrition, <17 indicates malnutrition) (27).

The presence of a urinary tract infection was confirmed by a positive urine culture. Heart failure was confirmed by the presence of specific signs and symptoms and by ejection fraction (EF ≥ 50% - preserved

EF; EF < 50% - reduced EF), and the presence of osteoarticular pathology was evident from the patients' previous medical records. Emotional status was assessed using the 15-item Geriatric Depression Scale (GDS), with scores below 5 considered normal, 5–8 as mild depression, 9-11 as moderate depression, and above 11 as severe depression (28). The adapted Physical Resilience Scale was interpreted as follows: low resilience (score 1-5), moderate resilience (score 6-10), and high resilience (score 11-15) (16). The questionnaires were completed after obtaining the patient's informed consent and were administered by the same trained medical team.

Data were collected by a geriatric team and analyzed using SPSS Statistics 25 and Microsoft Office Excel/Word 2024. The Shapiro-Wilk test, the Mann-Whitney U/Kruskal-Wallis H test (with Dunn-Bonferroni post-hoc tests), Spearman's rho correlation coefficient, and univariate and multivariate generalized linear models using the Poisson method and the forward step-wise Wald method were performed. Statistical significance was defined at a 95% confidence interval ($p < 0.05$).

RESULTS

The study included 110 patients, with the majority being women (63.6%). The mean age was 75.94 ± 6.87 years (median=76), with 47 patients (42.7%) under the age of 75 (younger adults) and 50 patients (45.5%) between the ages of 75 and 84 (middle-aged adults), and 13 patients (11.8%) (older adults) (tab. I).

Most patients had no risk of malnutrition (median MNA 23 (20.5-25.3)), normal cognitive status (median MMSE 27 (24-29)), somewhat depressed status (median GDS 5 (3-8)), and independence in performing simple activities of daily living (ADL, median 5 (5-6)) and instrumental activities of daily living (IADL, median 7 (5-8)).

Furthermore, the study group exhibits frailty (Freid Phenotype median 3 (2-4)) (tab. I). In terms of resilience, the study group has a median of 10 (8-13).

Furthermore, in the study group, normal muscle strength values were observed in the right arm relative to the left arm, and there were also fewer low values in the right arm compared to the left, which are interpreted in the context of the dominant upper limb (see Table I).

Of the three conditions studied, the highest proportion of patients had osteoarticular disease (69.1%), followed by decompensated heart failure (62.7%). Only 13.6% of the enrolled patients had a urinary tract infection (tab. I).

Moreover, data from our study shows significant and positive correlations of low/moderate power between the resilience scale and ADL ($p=0.022$, $R=0.218$), IADL ($p<0.001$, $R=0.397$), SPPB ($p<0.001$, $R=0.458$), MNA ($p<0.001$, $R=0.377$), MMSE ($p=0.001$, $R=0.322$), left arm muscle force ($p<0.001$, $R=0.335$) or right arm muscle force ($p=0.001$, $R=0.332$), showing that patients with higher values for these parameters were significantly associated with higher values for the resilience scale and vice versa (tab. II). Also, there are significant and negative correlations of low/moderate/high power between the resilience scale and falling risk ($p<0.001$, $R= -0.331$), GDS ($p<0.001$, $R= -0.676$) or Fried phenotype score ($p<0.001$, $R= -0.462$), showing that patients with higher values for these parameters were significantly associated with lower values for the resilience scale and vice versa (tab. II).

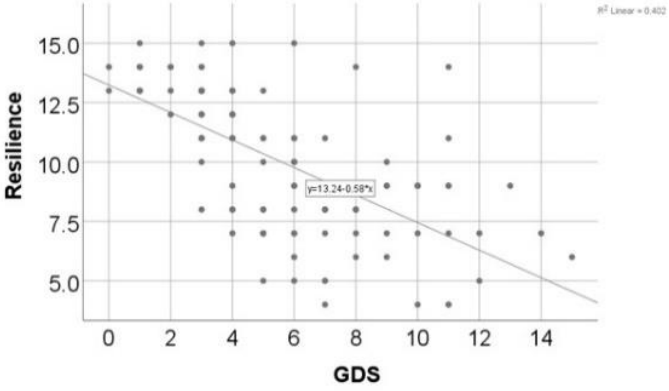

Fig. 2. Correlation between resilience scale and GDS

Table III and figures 3 and 4 present a comparison of the resilience scale in relation to the presence of heart failure, osteo-articular disorders, infection, and muscle strength in the study patients. The results showed that resilience did not differ in relation to these conditions: heart failure (p=0.171), urinary tract infection (p=0.517), and osteo-articular conditions (p=0.120). Patients with lower muscle force had significantly lower values for the resilience scale than patients with normal muscle force (p = 0.002 / p = 0.005). Furthermore, resilience differed significantly in relation to muscle strength: resilience (median 10 (8-13)).

Lower	8.47 ± 2.72	8.5 (7-10.75)	39.92	

*Mann-Whitney U Test, **Kruskal-Wallis H Test, MF-LA = Muscle force – left arm, MF-RA = Muscle force – right arm; CHR – chronic heart failure; UTI – urinary tract infection

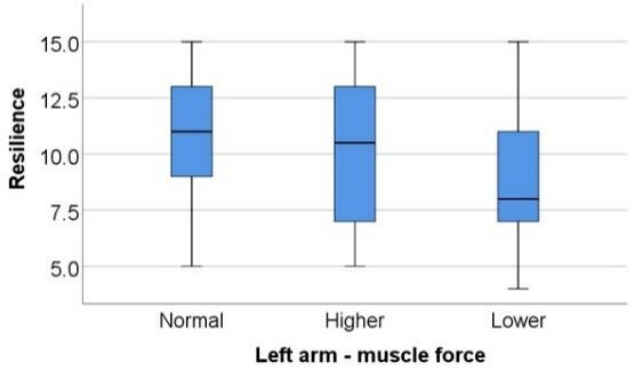

Fig. 3. Comparison of resilience scale according to the muscle force at the left arm

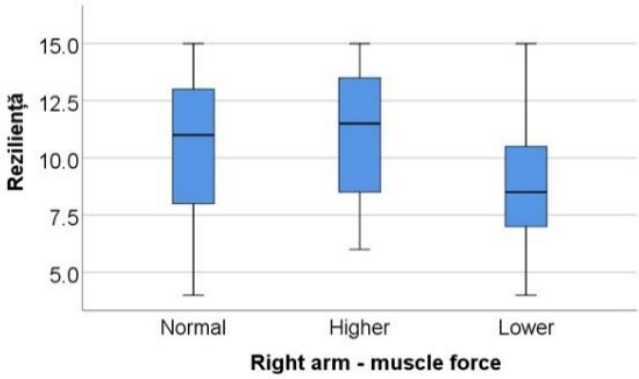

Fig. 4. Comparison of resilience scale according to the muscle force at the right arm

The univariable and multivariable generalized linear models used in the prediction of resilience scale are shown in table IV. According to the data from the multivariable model, the results show the following:

- The increase of one point for the IADL score increases the resilience scale by 3.2% (IRR = 1.032, 95% C.I. = 1.001-1.064, p=0.043).
- The increase of one point for the GDS score decreases the resilience scale by 5.7% (IRR = 0.947, 95% C.I. = 0.927-0.966, p<0.001) (tab. IV).

Physical resilience was positively associated with functional and nutritional status, including ADL, IADL, SPPB, upper-limb muscle strength, and MNA, with significantly lower resilience observed in patients with reduced muscle force. Psychological resilience correlated positively with cognitive status as measured by MMSE. Emotional resilience demonstrated a strong negative association with depressive symptoms (GDS), indicating that higher depression scores are linked to markedly lower resilience. Social resilience appeared indirectly related to functional autonomy (particularly IADL) and thus to social participation and network engagement, with IADL emerging as an independent predictor of resilience.

TABLE IV.
Univariable and multivariable generalized linear models used in the prediction of resilience scale

Parameter	Univariable		Multivariable*	
	IRR (95% C.I.)	p	IRR (95% C.I.)	p

DISCUSSION

The present study demonstrates that resilience in older adults is closely linked to multiple domains of geriatric assessment, including functional status, physical performance, nutritional state, cognitive function, and muscle strength. At the same time, resilience is inversely associated with depressive symptoms, fall risk, and frailty. These findings reinforce the conceptualization of resilience as a multidimensional construct that integrates physical, psychological, and functional components.

The strong positive association between functional independence (ADL/IADL) and resilience is consistent with current research emphasizing the central role of autonomy in successful aging. Recent studies have shown that preservation of IADL is a key determinant of psychological resilience, as it reflects not only physical capacity but also executive function and social participation (29, 30). Loss of independence has been associated with diminished self-efficacy and reduced coping resources, thereby negatively impacting resilience trajectories in older populations.

The observed relationships between physical performance (SPPB), muscle strength, and resilience are also supported by emerging evidence linking sarcopenia and mobility limitations to reduced adaptive capacity. An increasing number of studies indicates that physical frailty and sarcopenia are not only biological conditions but also predictors of psychological vulnerability (31, 32, 33). In this context, better physical performance may contribute to resilience by preserving autonomy, reducing disability risk, and maintaining engagement in daily and social activities.

Similarly, the positive associations between nutritional status and cognitive function with resilience align with recent findings highlighting the interplay between metabolic, neurological, and psychological

health. Malnutrition and cognitive impairment have both been independently associated with decreased resilience and increased vulnerability to stressors (34, 35). Adequate nutrition supports brain function and energy balance, while preserved cognition enhances problem-solving abilities and adaptive coping strategies.

One of the most reliable findings of this study is the strong inverse relationship between depressive symptoms and resilience. This is consistent with current literature demonstrating a bidirectional association between depression and resilience in older adults (36). Depressive symptoms undermine coping mechanisms, reduce motivation, and impair social functioning, all of which are critical components of resilience. Importantly, our multivariable analysis confirms that depressive symptoms remain an independent predictor, underscoring their central role in resilience frameworks.

The negative association between frailty, fall risk, and resilience further supports the notion that resilience is deeply embedded within the broader frailty concept. Previous studies suggest that resilience may act as a protective factor mitigating the progression of frailty and its adverse outcomes (29, 31).

In contrast, frailty contributes to a cycle of decline characterized by reduced physical reserve, increased dependency, and heightened psychological distress.

From a clinical standpoint, these findings highlight the importance of adopting a comprehensive, multidimensional approach to geriatric care. Interventions targeting physical rehabilitation, nutritional support, cognitive stimulation, and mental health particularly depression screening and management may have synergistic effects on both resilience and overall health outcomes. Integrated care models have been shown to improve functional status and quality of life while reducing hospitalization and institutionalization rates (1, 37).

Notably, the identification of IADL and depressive symptoms as independent predictors of resilience suggests that these domains may represent key therapeutic targets. Programs aimed at maintaining or restoring functional independence, alongside early detection, and treatment of depression, could play an essential role in enhancing resilience and promoting healthy aging.

CONCLUSIONS

This study underscores that resilience in older adults is a complex, multidimensional construct, intimately linked to functional autonomy, physical performance, cognitive and nutritional status, and muscle strength, while inversely associated with depressive symptoms, frailty, and fall risk. Functional status and depressive symptomatology emerged as independent and robust determinants, highlighting that resilience is strongly shaped by both functional independence and mental health. These findings emphasize resilience not merely as a psychological trait but as a central factor influencing adaptive capacity and overall health in aging populations. Multidomain interventions aimed at preserving functional abilities and addressing depression may therefore substantially enhance resilience and mitigate vulnerability to adverse outcomes. Longitudinal studies are needed to clarify causal pathways and assess the effectiveness of strategies designed to strengthen resilience in elderly.

REVERSE LEFT ATRIAL REMODELING ASSESSMENT AFTER PAROXYSMAL ATRIAL FIBRILLATION ABLATION: OUR FIRST EXPERIENCE (Abstract) We aimed to assess reverse left atrial (LA) remodeling at 6 months after ablation of paroxysmal atrial fibrillation (AF), and to identify the most relevant parameter of reverse LA remodeling. **Material and methods**: Left atrial size was assessed by echocardiography: antero-posterior (AP) diameter, LA area in apical 4 and 2 chambers (A4c, A2c), LA volume by biplane formula (LAV1), and by computed-tomography (LAV2). **Results:** Seventy-eight consecutive patients with mean age of 57.41 ± 8.05 years were prospectively included; 60 (76.9%) were with paroxysmal AF less than 24 hours and 18 (23.1%) less than 7 days duration. All echocardiographic and computed-tomographic evaluations were made within 4 weeks before ablation and at 6 months after ablation procedure by the same operator. Circumferential or segmental pulmonary vein isolation was performed by radiofrequency in 58 (74.4%) patients, and by cryotherapy in 18 (23.1%) patients. At 6 months 53 (67.9%) patients were in stable sinus rhythm and 18 (23%) out of those on antiarrhythmic drugs. At 6 months after ablation all parameters of LA size decreased statistically significant. **Conclusions:** In our first experience, endocardial catheter ablation results in significant conversion in sinus rhythm in patients with paroxysmal AF. The maintenance of stable sinus rhythm after ablation procedure determined a significant reverse LA remodeling, irrespective of parameter used for LA size assessment. The most relevant parameter for assessing reverse LA remodeling in patients with endocardial ablation of paroxysmal AF was LA volume by echocardiography. **Keywords:** ATRIAL FIBRILLATION, LEFT ATRIUM, VOLUME, REMODELING.

Discovering of the pulmonary vein role as triggers in atrial fibrillation (AF) initiation and maintenance was fundamental for its therapy (1). Pulmonary vein isolation by catheter ablation is nowadays a well-known curative technique in selected patients (2, 3). After AF onset, structural, electrical and mechanical remodeling of the left atrium (LA) facilitates its own perpetuation ("AF begets AF") (4). LA size is an important marker of structural remodeling, recommended by current guidelines (5). LA size can be assessed by anterior-posterior diameter, area or volume; the current echocardi-

ographic recommendation being area or volume as parameters of LA remodeling assessment (6). It is well-known that echocardiography underestimates and computed-tomography (CT) overestimates LA volume (5).

It is well-known that stable sinus rhythm maintenance after AF ablation means reverse structural LA remodeling occurrence (decreasing LA size). It is associated with better outcomes in patients underwent AF ablation.

We aimed to assess reverse left atrial (LA) remodeling at 6 months after paroxysmal AF ablation and to identify the most relevant parameter of reverse LA remodeling.

MATERIAL AND METHODS

In this single center study, patients with paroxysmal or persistent AF were selected to undergo pulmonary vein isolation using first generation cryoballoon or by means of radiofrequency. Patients selection and inclusion in the study was made according with the current guidelines (2,3). The ablation procedure consisted of endocardial ostial isolation of each PV antrum by radiofrequency energy using a Lasso™ catheter (BiosenseWebster, CA, USA) and an irrigated tip Celsius™ Thermo Cool (Biosense Webster, CA, USA) or cryoablation (ICE® Cryoablation System, Medtronic, USA). Both procedures were done using local anesthesia by femoral access and deep sedation with Morphine fractionated i. v. during application of energy.

Left atrial size was assessed by echocardiography: antero-posterior diameter (AP), LA area in apical 4 and 2 chambers (A4c, A2c), LA volume by biplane formula (LAV1), and by computed-tomography (LAV2). All echocardiographic and CT measurements were made within 4 weeks before ablation and at 6 months after ablation procedure by the same operator.

Echocardiographic evaluation of left atrium size

Transthoracic echocardiography is the recommended approach for assessing LA size. Left atrial AP diameter (fig. 1), LA area in 4 and 2 apical chamber view and LA volume by biplane area-length formula (fig. 2) measurements were done using two-dimensional (2D) transthoracic echocardiography with an IE33 machine (IE 33 Echocardiography System, Philips Healthcare, The Netherlands). All echocardiographic measurements were performed at end-ventricular systole, at maximal LA size (for maximal LA volume assessment).

As currently recommended, we optimized each view to avoid: an underestimation of LA volume by foreshortening of the major length of the LA, inaccurate assumption of the mitral annulus boundary, loss of lateral resolution of the LA wall in the apical view or dropout of the interatrial septum or anterior wall (5). All measurements by echocardiography were performed by the same operator, before and at 6 months after ostial endocardial AF ablation.

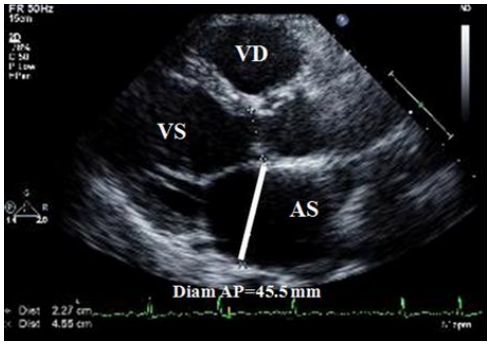

Fig. 1. Left atrium anterior-posterior diameter measurement in parasternal long-axis view by bi-dimensional transthoracic echocardiography

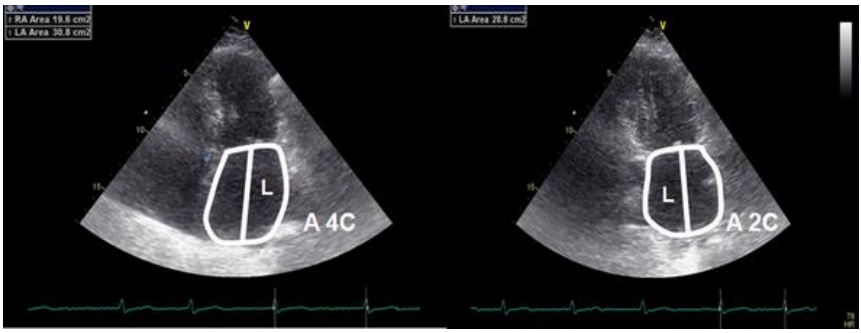

Fig. 2. Left atrium area and volume measurement in 4 and 2 chambers view by bi-dimensional transthoracic echocardiography *(A4C: apical four chamber views; A2C: apical two chamber views; L: length)*

Computed tomographic evaluation of left atrium volume

All patients underwent cardiac contrast enhanced CT (Siemens Somatom Senzation 128-Slice Configuration, Siemens AG, Germany) for evaluation of the morphology of the left atrium, before AF ablation and at ± 6 months after this procedure. For maximal LA volume assessment, all CT images were ECG-gated. We applied the ellipsoid biplane area-length formula, after we obtained an optimal contour in transverse axis by tracing the endocardial border cavity (fig. 3). Each of the CT slices was performed at 1 mm so L dimension was equal with the totally number of the slices.

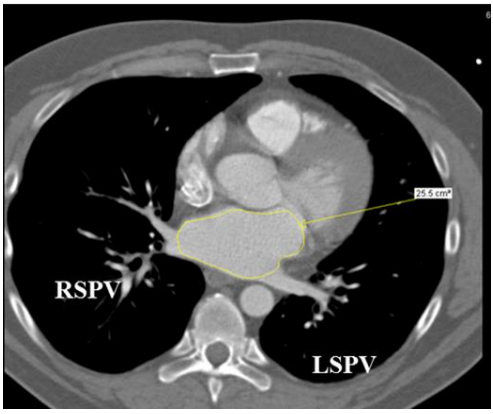

Fig. 3. Computed tomography image in axial view of left atrial volume measurement (*RSPV - right superior pulmonary vein, LSPV- left superior pulmonary vein*).

We performed the measurements avoiding an overestimation of LA volume on CT, by the following: the inclusion of part of LA appendage volume, the incorporation of the PV or overlap and the duplicate measurements of the multiple sequence scans. All measurements on CT were performed by the same operator, before and at 3 months after ostial endocardial AF ablation.

Statistical analysis

Data are presented as frequency distributions and simple percentages. Continuous variables are expressed as mean ± standard deviation. Statistical analysis was performed using *SPSS 10* for Windows (SPSS Inc., Chicago, IL, USA). A p value <0.05 was considered significant.

RESULTS

Seventy-eight consecutive patients undergoing non-valvular AF catheter ablation were prospectively and consecutively included in this study; 60 (76.9%) out of these patients were with paroxysmal AF less than 24 hours and 18 (23.1%) with paroxysmal AF less than 7 days. Mean age

was 57.41 ± 8.05 years; 67% were men; 74% had have arterial hypertension, 33% coronary heart disease and 19% diabetes mellitus. Mean paroxysmal AF duration was 4.7±1.7 months.

Circumferential or segmental pulmonary vein isolation was performed by radiofrequency energy in 58 (74.4%) patients and by cryotherapy in 18 (23.1%) patients. Antral pulmonary vein isolation was obtained at 35W (by radiofrequency energy) and minus 40°C (by cryotherapy). In patients with paroxysmal AF longer than 24 hours we used exclusively radiofrequency energy and ablation procedure was completed by complex fractionated atrial electrogram and cavo-tricuspid istmus ablation (if common atrial flutter was confirmed before or during procedure).

At 6 months 53 (67.9%) patients were in stable sinus rhythm, 18 out of these patients being on antiarrhythmic drugs. A redo (a second procedure) procedure was made in 23 (29.5%) patients and 18 (78.3%) of these patients were converted in stable sinus rhythm until 6 months. At 6 months, all parameters for LA size decreased statistically significant (tab. I).

TABLE I.

Mean values of left atrial parameters assessing left atrial size at baseline and after 6 months post-ablation

PARAMETERS	BASELINE	AFTER 6 MONTHS	p
Anteroposterior diameter (AP); mm	42±7	40±8	**0.050**
Apical 4 chamber area (A4c); cm^2/m^2	26±7	23±6	**0.003**
Apical 2 chamber area (A2c); cm^2/m^2	26±8	24±6	**0.011**
Indexed left atrial volume by biplan formula (LAV1); ml/m^2	44±16	37±10	**0.010**
Indexed left atrial volume by computed-tomography (LAV2); ml/m^2	49±23	44±17	**0.026**

DISCUSSION

Catheter ablation is now an accepted procedure for the treatment of AF (2, 3). In AF patients LA dilation is a marker of LA structural remodeling. This could result in a changed LA morphology and shape with a larger LA area and volume. LA volume and area and shape are the best parameters for LA size assessment as marker of LA structural remodeling.

The atrium dilation has different consequences over the LA anatomic segments (5). The mitral annulus, the mitral-aortic junction and the interatrial septum are less susceptible to dilatation because they are relatively fixed. Because of lack of the fibrous component, the pulmonary vein antrum could modify their thickness and geometry in structural remodeled atria (7,8). Progressive LA dilation is associated with asymmetrical structural remodeling and shape changes (5,8). Recently it was shown that a remodeled LA during dilatation evolved from ellipsoidal shape through a spheroidal one. This spheroidal shape could be an independent predictor of recurrence after AF ablation and may be useful in selecting the best candidates for AF ablation (9).

The most widely used parameter for LA size assessment, AP linear dimension, should not be used as the sole measure of LA size (5). If is still used, 2D echocardiog-

raphy in parasternal long-axis view is preferred over M-mode echocardiography (5).

When assessing the LA size and remodeling, the measurement of LA volume is recommended, because it considers alterations in LA chamber size in all directions. Two-dimensional echocardiographic LA volumes are typically smaller than those reported from CT or magnetic resonance imaging (5). Different methods exist for measuring LA volumes. Although the three linear measurements have been used to calculate LA volume using an ellipsoid model, the relative inaccuracy of these linear measurements limits this method. LA volume should be measured using the disk summation algorithm.

The LA endocardial borders should be traced in both the apical four- and two-chamber views. A single-plane approach can also be used, but this method is based on the geometric assumption that the LA is circular in the short-axis cut plane, which may not be always accurate. Although not recommended for routine use, this approach could be used in cases when planimetry in both views is difficult. Single-plane apical four-chamber indexed LA volumes are typically 1 to 2 mL/m2 smaller than apical two-chamber volumes (5). Alternatively, a bi-plane calculation could also be performed using the LA areas and lengths measured from both the apical four- and two-chamber views. Although the area-length method still assumes an ellipsoidal LA shape, it has the advantage of reducing linear dimensions to only two measurements of atrial length, of which the shorter one is selected.

All parameters used to assess LA size decreased statistically significant after 6 months; it means that LA suffered a reverse remodeling after catheter ablation of AF. The most significant reducing was unregistered of LAV1 (16%) comparing with 12% for A4C, 11% for LAV2, 10% for AP diameter and 8% for A2C. Therefore, we consider LAV1 or LA volume by echocardiography (bi-plane area-length formula) the most relevant parameter for assessing reverse LA remodeling in patients with endocardial ablation of paroxysmal AF.

Mean LA volume by echocardiography was smaller than by CT; it confirms that echocardiography might underestimates and CT might overestimate LA volume.

Echocardiography with the ellipsoid bi-plane dimension-length formula, is one of the recommended methods by both echocardiographic recommendations (5,6) although implying a certain degree of volume underestimation. Usually all patients selected for AF catheter ablation underwent a CT exam because of pre-procedural and intra-procedural utility.

However, echocardiography comparing with CT is cost efficient avoids irradiation exposure and is easier to use in daily practice.

Lower LA appendage contraction velocity could be a non-invasive pre-procedural predictor of persistent AF recurrences after ablation, indicating the possibility of reduced reverse remodeling of the LA (10).

Reverse structural remodeling takes longer and is still present 2 to 4 months after restoration of sinus rhythm (11). Pre-procedural delayed enhancement magnetic resonance imaging is also able to determine the degree of atrial fibrosis and is another tool to predict the reverse remodeling after ablation.

Study limits

This study was mainly designed to assess LA reverse structural remodeling in patients with non-valvular underwent AF

catheter ablation. In this study, we did not use any software for CT volume measurements. By performing single operator evaluations, we avoided inter- but not intraoperatory variability. Left atrial volume, as marker of structural remodeling, was assessed before and 3 months after AF ablation. It is difficult to discuss the influence of the type of ablation energy during AF ablation technique on LA volume, because the reduced number of patients; in addition, the follow-up was only 6 months.

CONCLUSIONS

Endocardial catheter ablation results in significant conversion on sinus rhythm in patients with paroxysmal AF. The maintenance of stable sinus rhythm after ablation procedure determined a significant reverse LA remodeling, irrespective of parameter used for LA size assessment. The most relevant parameter for assessing reverse LA remodeling in patients with endocardial ablation of paroxysmal AF was LA volume by echocardiography.

BREAST CANCER AND BASAL CELL CARCINOMA IN THE SAME PATIENT - IS IT RANDOM? (CASE SERIES REPORTS) (Abstract): Non-melanoma skin cancer, including basal cell carcinomas and squamous cell carcinomas, is the most common cancer affecting white-skinned individuals and its incidence is increasing worldwide. Several studies have reported that individuals diagnosed with non-melanoma skin cancer are at higher risk of subsequent or prior diagnoses of second primary malignancies. We report a series of five cases with concomitant basal cell carcinoma and breast cancer; in two cases the basal cell carcinoma was diagnosed after the breast cancer and in three cases it preceded it. Considering the high frequency and low mortality of basal cell carcinomas, they offer an excellent opportunity to study the factors that put some individuals at increased risk of multiple malignancies.
Keywords: BREAST CANCER, BASAL CELL CARCINOMA, NON-MELANOMA SKIN CANCER, MULTIPLE MALIGNANCIES.

Non-melanoma skin cancer (NMSC) is the most common cancer affecting white-skinned individuals and its incidence is increasing worldwide (1). The two major types of NMSC, basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), have a relatively small impact on mortality but their public health impact is considerable. Although they share many similarities, they have different incidence rates and important etiological differences (2, 3).

In comparison with other malignancies, information regarding the incidence of NMSC and BCC is limited due to poor registration practice in most of countries, including Romania (4). The incidence rate appears to be higher compared with other malignancies and it is increasing. Worldwide the incidence of NMSC varies widely with the highest rates in Australia (>1,000/100,000 person-years for BCC) and the lowest rates in parts of Africa (<1/100,000 person-years for BCC) (1). Although the reason for this is unclear, in some countries it may be linked to increased sun-seeking behaviors and improved registration procedures (1).

Several studies have reported that indi-

viduals diagnosed with BCC are at higher risk of subsequent or prior diagnoses of second primary malignancy by about 20-60% (5).

In 2012, the estimated age-adjusted annual incidence of breast cancer in 40 European countries was 94.2/100,000 and the mortality 23.1/100,000, with rather decreased values for Romania: significantly lower incidence of 66.2/100,000 and similar mortality of 21.6/100,000 (6), possibly due to delay in or avoidance of seeking medical attention and advanced stage at diagnosis. Since breast cancer is the most frequently diagnosed non-cutaneous cancer among women, it is not surprising that many individuals with breast cancer will associate BCC.

During a prospective study on breast cancer comprising of 65 patients, we identified 8 patients that associated multiple malignancies, of which 5 (7.7% of all cases) associated basal cell carcinomas. We present the particularities of these 5 patients.

CASES REPORTS

Case 1. Female patient, aged 77, was diagnosed with malignant tumor of the left mammary gland in September 2013, which was surgically removed (superior-external quadrantectomy with lymphadenectomy - 13 lymph nodes) and morphopathological examination revealed an invasive carcinoma of the mammary gland with mucinous areas, stage pT2N0G1 (tab. I). The patient received subsequent radiotherapy and is now continuing treatment with hormone therapy (Tamoxifen).

In July 2015, the patient underwent surgical removal of a white nuanced frontal lesion with central ulceration, which appeared one year before surgery. The anatomo-pathological examination revealed that the lesion measuring 0.7/0.6/0.1 cm was a superficial multicentric basal cell carcinoma and confirmed the excision was in the healthy tissue in all plans (tab. II).

Case 2. Female patient, aged 69, was diagnosed with malignant tumor of the right mammary gland in December 2004. Subsequent surgery (Madden modified radical mastectomy, including lymphadenectomy of 8 lymph nodes) followed by the morpho pathological examination identified NOS invasive ductal carcinoma, stage pT1cN2aMxG3 (7 lymph nodes with metastases, 2 lymph nodes > 2cm) (tab. I). The treatment included chemotherapy and radiotherapy, followed by hormone therapy (3 years with Tamoxifen and 2 years of Letrozole).

In September 2015 the patient underwent surgery for a white skin lesion in the nasal region, which appeared 3 years earlier and in the absence of clinical improvement the patient sought medical attention. Surgery was performed and morpho pathological examination revealed a lesion measuring 0.7/0.6 cm corresponding to a superficial multicentric basal cell carcinoma. The examination also confirmed the excision was made in healthy tissue in all the plans (tab. II).

Case 3. Female patient, aged 77, was diagnosed with malignant tumor of the right mammary gland in December 2009 when surgery was performed (Madden modified radical mastectomy, including lymphadenectomy of 7 lymph nodes). The morphopathological examination identified NOS invasive ductal carcinoma, stage pT1bN0MxG2 (tab. I). The treatment included chemotherapy followed by hormone therapy (5 years of Letrozole).

In this case, the history of skin lesions preceded the diagnosis of mammary gland tumor. From patient's data, the first skin lesion appeared around the age of 22

(1968), after a severe sunburn, under the form of a pigmented asymmetrical lesion localized in the left suprascapular region that began to ulcerate and was surgical removed in 2004. The morphopathological examination confirmed a basal cell carcinoma. Four years later, in the proximity of the first lesion, in the posterior cervical region, another lesion appeared and was rapidly surgically removed. The morphopathological examination revealed another lesion of basal cell carcinoma, and confirmed the surgery was performed within oncological safety limits (tab. II).

Case 4. Female patient, aged 62, known with malignant tumor of the left mammary gland that was surgically removed in August 2006 (Madden modified radical mastectomy, including lymphadenectomy of 19 lymph nodes) followed by the morphopathological examination that identified invasive tubular carcinoma, stage pT2N2aMx-G1 (7 lymph nodes with metastases) (tab .I), underwent chemotherapy and afterwards hormone therapy (3 years Letrozole, 1 year Tamoxifen and is currently on 6-month treatment with Exemestane).

In November 2015 the patients underwent surgery for a skin lesion localized in the nasal region that appeared approximately 12 years before. The morphopathological examination revealed a lesion corresponding to a solid ulcerative basal cell carcinoma, with pigmented areas (fig. 1). The examination also confirmed the excision was made in healthy tissue in all plans (tab. II).

Case 5. Female patient, aged 65, diagnosed with malignant tumor of the left mammary gland and operated in January 2013 (Madden modified radical mastectomy, including lymphadenectomy of 33 lymph nodes) and the morphopathological examination identified NOS invasive ductal carcinoma, stage pT2mN2aMxG2 (tab. I). The treatment included chemotherapy and radiation therapy followed by hormone therapy (Letrozole).

The patient reported in 2001 a pathological skin lesion located on the face (left temporal region) that was surgically removed simultaneously with the breast lesions. The morphopathological examination confirmed a solid basal cell carcinoma with an ulcerative area (tab. II).

DISCUSSION

We presented five cases associating two primary malignancies: BCC and breast cancer. Considering that our ongoing research included 68 patients with breast cancer, this association was met in 7.4% of the patients. This raised the question of possible underlying mechanisms that lead to this condition.

BCC seems to form in the epidermal stem cells of the outer root sheet of the hair follicle, but the precise origin of BCC it is still unknown. The lesions are classified into five types: nodular-ulcerative, pigmented, sclerodeiform or fibrosing, superficial and fibroepithelioma. Apart from the environmental exposure and immunosuppressive therapy, people with a fair skin type-I complexion (red or blonde hair, light colored eyes, freckles), and those with a history of intermittent sun exposure, especially ultraviolet (UV) - B radiation and severe sunburn during childhood, are at highest risk (7). The treatment options are focused on local control and include mainly surgical techniques. Nonsurgical approaches comprise of radiotherapy, topical injection therapy and photodynamic therapy (8, 9).

Regarding breast cancer, this is a heterogeneous disease with histological differences within tumors and between patients. The cancer development in the normal mammary gland depends on stem cells,

neighboring cells including fat cells and fibroblasts that play distinct roles through specific signaling pathways (10). Endogenous hormones (sex hormones, growth hormone axis), reproductive factors (lower parity, older age at first giving birth, younger age at menarche, older age at menopause), oral contraceptives and hormone replacement therapy, family history and genetic factors (BRCA1 and BRCA2 mutations), alcohol and smoking, diet, overweight and obesity are known to be risk factors in breast cancer (11). The treatment of breast cancer includes surgery, radiation therapy, chemotherapy, and hormone therapy and the prognosis and selection of therapy may be influenced by clinical and pathological features.

It is likely that the association of BCC and other cancers may have an etiologic link. The deficiencies of pathways responsible for protecting against cellular transformation in multiple tissues, such as DNA repair (e.g.: nucleotide excision repair - NER - pathway) (12,13,14) or immune responses (e.g.: UV-induced immunosuppression) (15,16), may play a role in cutaneous and internal carcinogenesis.

The major environmental cause of BCC is exposure to solar UV radiation (17, 18). The individual risk appears to be determined largely by cumulative exposure to solar radiation, in combination with individual susceptibility. Thus, it is important to realize that BCC incidence is based on a lifetime of exposure to risk factors, and the older population that is currently being diagnosed used very little sun protection and received very little education regarding the effects of ultraviolet radiation (UV) (19). On the other hand, the exposure to UV-B radiation is necessary to provide sufficient vitamin D, known to reduce the risk of cancer incidence, but data considering this issue are conflicting (19,20).

Breast cancer after BCC

In addition to having an increased risk for new skin cancer, patients with basal-cell carcinoma are at increased risk for non-cutaneous cancer at various sites.

In one of the largest prospective cohort study on topic (18) (performed in U.S.A.; included 107339 women, 46237 men), the researchers found that among patients with a personal history of NMSC (without specification to BCC or SCC) there was an increased risk of subsequent malignancies, specifically breast (RR = 1.19; 95% CI 1.11-1.28, $p<0.0001$; AR = 87 per 100,000 person-years) and lung (RR=1.32, AR=22 per 100,000 person-years) cancer in women and melanoma in both men (RR=1.11; 95% CI 1.05-1.18) and women (RR=1.20; 95% CI 1.15-1.25). They also showed that patients with medical history of NMSC were more likely to be older and tended to burn and have more severe sunburns.

In population-based case-control study on NMSC (U.S.A) (5) (3584 participants: 1543 individuals with BCC, 1170 with SCC, 1416 age- and sex-matched controls) a significantly increased cancer risk after BCC was identified, that could not be explained by a variety of environmental, nutritional or behavioral risk factors, or by family history of cancer (adjusted HR=1.4, 95% CI 1.15, 1.71). In the site-specific analysis, BCC was associated with an increased risk of subsequent breast cancer (adjusted HR=1.13, 95% CI 0.62, 2.06).

A population-based cohort study (21) (Denmark; it included 37,674 patients followed for a maximum of 14 years after a first diagnosis of basal-cell carcinoma) showed that patients diagnosed with basal-

cell carcinoma before 60 years of age (SIR=1.26) had a statistically higher risk for developing new cancer (P < 0.01) than did those diagnosed at 60 years of age or older (SIR=1.11). Also, the study revealed that patients with BCC had an increased risk of developing breast cancer, and that this risk was also significantly affected with age (SIR=1.37 in patients < 60 years of age compared with 1.05 in those > or = 60 years of age).

Another study (22) (Canada, 15,586 cases of BCC and SCC) reported a greater risk of female breast cancer following a BCC. Overall, the increased risk of developing a subsequent cancer was observed only in the first 4 years following a NMSC, although it remained increased for specific cancer sites and that the risk remained higher in all age groups up to 75 years of age. For breast cancer, the standard incidence ratios for developing the second primary cancer varied by time since diagnosis: SIR=1.47 for <1 year from BCC, SIR=1.26 for 1-4 years and SIR=1.22, for >5 years; the total SIR was 1.22 (95% CI 1.11-1.34).

BCC after breast cancer

Besides an elevated risk of contralateral breast cancer, women with a primary breast cancer are at increased risk of developing a subsequent non-breast cancer (attributed to genetic and other risk factors, and treatment: radiotherapy, chemotherapy and hormonal therapy).

Data concerning the incidence of BCC in breast cancer patients is scarce, due to mostly various registrations (regarding NMSC some registries include all types, others include only SCC, while others have no data on NMSC).

A cohort study (23) (13 population-based cancer registries in Europe, Canada, Australia and Singapore; included 525.527 women with primary breast cancer) identified an increased risk of NMSC (SIR=1.58). The variations on the time since first primary tumor and the age at breast cancer diagnosis are presented in table IV.

TABLE IV

SIRs for NMSC among 535.527 women with a first primary breast cancer by time since first primary breast cancer and by age at breast cancer diagnosis (23)

	<1 year after breast cancer	1-9 years after breast cancer	10+ years after breast cancer	Pre-menopausal breast cancer (45 years)	Peri-menopausal breast cancer (46-55 years)	Post-menopausal breast cancer (561 years)
NMSC	1.23, 95 % CI 1.10-1.39	1.55, 95 % CI 1.48-1.62	**1.77**, 95 % CI 1.67-1.87	**2.08**, 95 % CI 1.87-2.31	1.68, 95 % CI 1.55-1.82	1.51, 95 % CI 1.45-1.57

Recent studies focus more on the incidence of melanoma developing after a breast cancer diagnosis (SIRs ranging from 1.16 to 2.74) (24, 25, 26) and this risk was attributed especially to external radiation therapy (even at non-irradiated sites) (27).

In 2 cases of our 5 patients, which were diagnosed with BCC after breast cancer, the lesions were localized on the face (sun-exposed regions) and patients underwent radiotherapy as part of breast cancer management before the diagnosis of BCC.

Future knowledge about the impact of

risk factors and effects of treatment in breast cancer may add further explanations on the association of BCC, in addition to potential influences from increased surveillance and general cancer susceptibility.

CONCLUSIONS

In our study regarding breast cancer patients, 5 associated BCC. Unfortunately, extensive data on the incidence of BCC is unavailable in Romania. Due to their high frequency and low mortality, BCCs offer an excellent opportunity to study factors that put some individuals at increased risk of multiple malignancies. Thus understanding the shared risk factors that contribute to multiple malignancies may lead to new etiologic insights.

Also, knowing the risk of developing new primary cancers after breast cancer is important not only in relation to potential side effects of their cancer treatment, but also in relation to the possibility of shared etiology with other types of cancer.

CONSENT. This study was approved by the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy Iasi, Romania, and written informed consent was obtained from the patients for the research and publication of this study and any accompanying images.

PRIMARY HYPERPARATHYROIDISM: HORMONAL PROFILE AND RISK OF COMPLICATIONS (Abstract): **Aim**: to assess the role of vitamin D status on the metabolic profile and spectrum of complications at patients with primary hyperparathyroidism function of the vitamin D repletion status. **Material and methods**: transversal study involving 42 patients with primary hyperparathyroidism submitted to parathyroidectomy. We evaluated serum calcium, phosphate, serum PTH and $25OHD_3$, bone mineral density by dual-energy X-ray absorptiometry (DXA-Hologic) and history of bone fractures and renal lithiasis. Fifteen (35.7%) patients had episodes of kidney lithiasis, whereas 27 (64.26%) patients did not develop this complication. Twenty (47.6%) patients were diagnosed with osteoporosis whereas 22 (52.36%) patients had normal bone mass or osteopenia. Data between groups were compared using the t test and were considered significant at p values < 0.05. **Results**: Twenty-nine (62.5%) of the 42 patients had $25OHD_3$ in the range of deficiency (lower than 20 ng/mL) and 9 (28.12%) had severe $25OHD_3$ deficiency (lower than 10 ng/mL). Serum calcium and phosphate were similar irrespective of the presence or absence of complications. No differences were found between mean PTH and $25OHD_3$ levels of patients with or without osteoporosis. Patients with kidney lithiasis had, however, higher PTH (390 +/- 90 pg/mL *vs.* 209 +/- 64 pg/mL, p< 0.001) and lower $25OHD_3$ levels (12.8 +/- 6 ng/mL *vs.* 19.2 +/- 7.8 ng/mL, p < 0.05) than patients without kidney lithiasis. **Conclusions**: D hypovitaminosis accompanies frequently primary hyperparathyroidism. Patients with higher risk of kidney lithiasis seem to have higher PTH and lower $25OHD_3$ levels. **Keywords:** PRIMARY HYPERPARATHYROIDISM, HYPOVITAMINOSIS D, OSTEOPOROSIS

Primary hyperparathyroidism (pHPTH) is the result of increased secretion of parathyroid hormone (PTH). Almost 85% of cases of pHPTH are caused by a single adenoma (1). pHPTH is usually accompanied by high levels of the active form of vitamin D ($1,25(OH)_2D_3$), due to excessive stimulation of 1-α hydroxylase by PTH. Vitamin D deficiency has a high frequency in the general population, and in patients with pHPTH (2, 3). This coexistence may mask certain biochemical modifications in pHPTH, such as hypercalcemia, but does not diminish the risk of bone or kidney

stone complications caused by the overproduction of PTH (4).

The co-existence of hypovitaminosis D with pHPTH was moreover associated with an increased circulating PTH, larger parathyroid glands, accelerated bone turnover and higher risk of fracture (2,5-7). Patients submitted to parathyroidectomy despite low vitamin D levels prior to surgery seem to have a higher risk of hungry bone syndrome (5, 8, 9). Moreover, severe long-standing vitamin D deficiency leads per se to disorders of bone mineralization, causing skeletal deformations and poor bone quality, called osteomalacia (10). These modifications may be added to the direct impact of PTH excess on bone (11, 12). The consequences of vitamin D deficiency in patients with pHPTH and their appropriate management are presently not completely clear. Although vitamin D repletion may decrease certain risks such as the appearance of hungry bone syndrome after surgery, there is a fear among clinicians for aggravating hypercalcemia or hypercalciuric by vitamin D supplementation and even to worsen or mask bone damage in patients with pHPTH (9). The D repletion – related risks are however inconsistently proven.

We wanted to investigate the impact of vitamin D status on the metabolic profile, severity and risk of complications in patients with primary hyperparathyroidism.

MATERIAL AND METHODS

We performed a transversal study involving 41 female patients aged 30-80 years and 1 man, 57 years, diagnosed with pHPTH in the Endocrinology Department of "St. Spiridon" Hospital between January 2014-December 2015, and submitted to parathyroidectomy. Prior to enrolment all patients signed an informed consent, approved by the Ethical Committee of "Grigore T. Popa" University of Medicine and Pharmacy Iasi.

Patients underwent anamnesis (personal history of fragility fractures or urolithiasis) and clinical examination. A morning fasting blood sample was taken for the dosage of Calcium (Ca), phosphate (P) (spectrophotometric technique, with Roche commercial kits compatible with the automatic analyzer Cobas 6000, Roche), PTH and 25-OH-D_3 (chemiluminescence using the automatic analyzer Cobas e 411, Roche BV). 24-hour urine sample was used for the measurement of Ca and P excretion. Abdominal ultrasound was performed to observe the presence of renal lithiasis. BMD at lumbar (L1-L4) and hip regions was assessed by dual-energy X-ray absorptiometry technique (DXA, Hologic Delphi W), by a certified technician.

All results were expressed as mean +/- SD. Statistical analysis was performed with SPSS 18.0. For the statistical analysis were used: Paired Sample T-Test / F_{ANOVA}, χ^2 / Kruskal-Wallis test, Pearson' s simple correlations. Differences were considered significant for $P < 0.05$.

RESULTS

This study included 41 women (23-82 years) and 1 man (57-years-old).

PTH was higher than the reference ranges in all patients (median value of 406.92 pg/mL). PTH was higher in the 28 patients under 60 years old than in the 14 patients over 60 (481.05 *vs.* 252.94 pg/mL; p= 0.044).

29 (62.5%) patients had $25OHD_3$ in the range of deficiency (lower than 20 ng/mL) and 9 (28.12%) had severe vitamin D deficiency (lower than 10 ng/mL). Other 9 (28.12%) patients had low (insufficient, i.e.

between 20 and 30 ng/mL) levels of $25OHD_3$. Only four (9.37%) patients had $25OHD_3$ in the range of repletion (> 30 ng/mL) (fig.1).

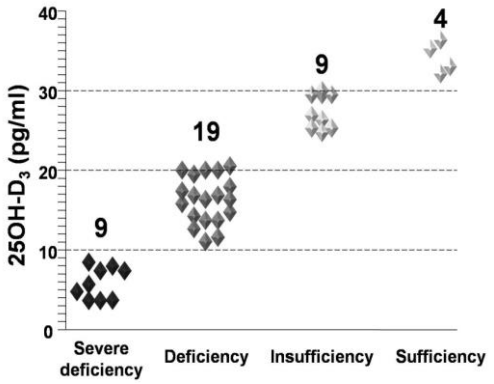

Fig.1. Vitamin D levels at patients with pHPTH

Low levels of vitamin D were associated with higher PTH in 65% of pHPTH patients (r=-0.65; p=0.009).

Serum calcium levels varied between 10.01–19.62 mg/dl (mean value 11.93 mg/dl) and was not significantly correlated with vitamin D levels (r= -0,194; p=0,288).

Serum phosphate was below reference ranges in 47.6% of patients, varying between 1.38-3.64 mg/dl (mean phosphate 2.40 mg/dl). Vitamin D was in direct correlation with phosphate levels, 47.1% of patients associating higher levels of phosphate with higher values of vitamin D (r= +0.471; p=0.008).

Median lumbar, femoral and forearm BMD were in the osteopenia/osteoporosis range for T-score and had no further loss one year after surgery (fig. 2a, b, c).

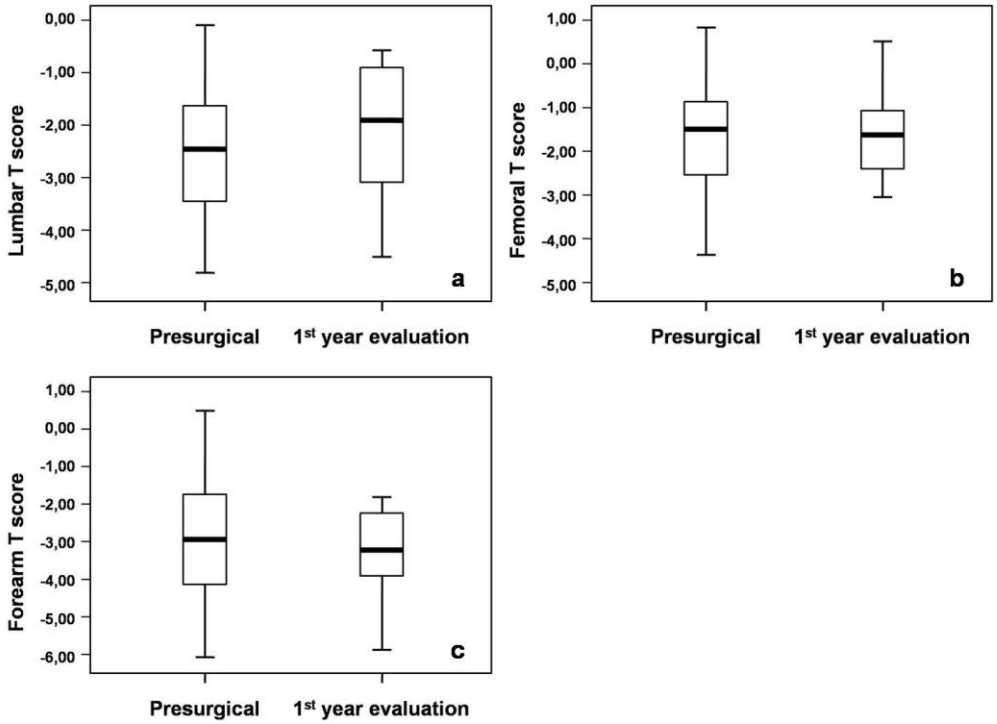

Fig.2. BMD expressed as T score before and one year after parathyroidectomy at lumbar (L1-L4) (**a**), femoral (**b**) and forearm level (**c**)

20 (47.6%) patients were diagnosed with osteoporosis, whereas 22 (52.36%) patients had bone mass in the range of normal or osteopenia.

PTH levels decreased drastically after surgery, suggesting cure. There were no significant differences between median values of pre- or postsurgical PTH from patients with or without osteoporosis (fig. 3a). Patients with hypovitaminosis D received vitamin D supplementation (1000 IU $25OHD_3$ per day), therefore median vitamin D increased significantly after one year ($p < 0.05$). We found no differences between median $25OHD_3$ levels from patients with or without osteoporosis before or one year after surgery (fig. 3b). Only 5 (11.9%) patients had a history of fragility fractures. Again, no differences in presurgical PTH or $25OHD_3$ levels were observed between patients with or without fragility fractures (fig. 3c, d).

Anamnesis revealed that 15 (35.7 %) patients had a history of renal lithiasis, whereas 27 (64.26%) patients did not develop this complication. Patients with renal lithiasis had higher PTH (390 +/- 90 pg/mL *vs.* 209 +/- 64 pg/mL, $p < 0.001$) and lower $25OHD_3$ levels (12.8 +/- 6 ng/mL *vs.* 19.2 +/- 7.8 ng/mL, $p < 0.05$) than patients without renal lithiasis (fig. 4a, b).

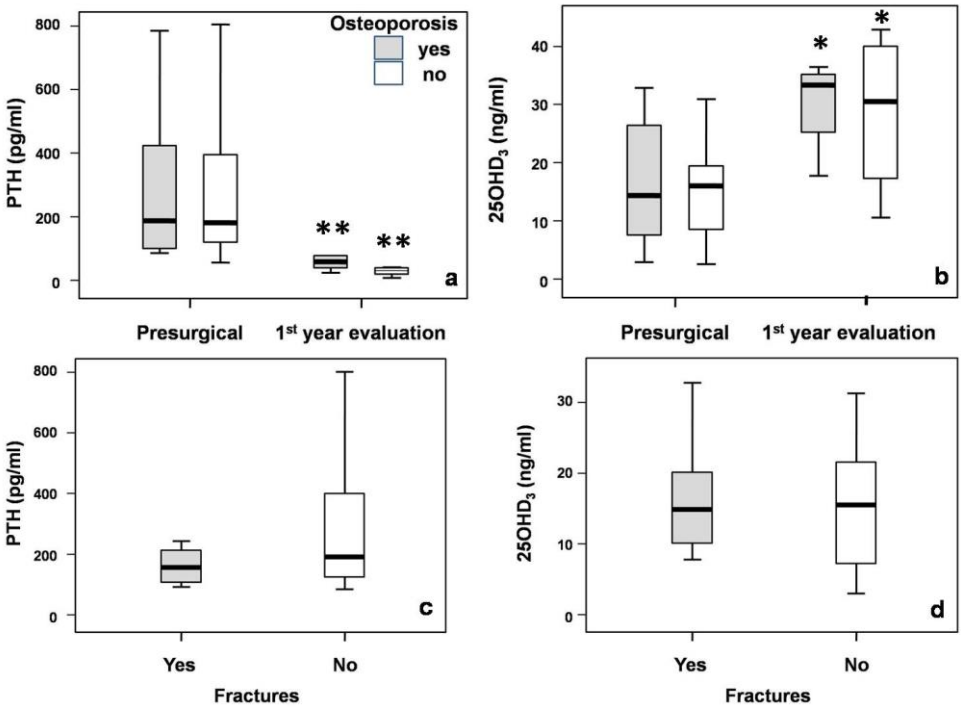

Fig. 3. a, b. Serum PTH and $25OHD_3$ before and one year after parathyroidectomy at patients without (white) or with (gray) osteoporosis (defined as having a T score lower than – 2.5 at one or more situses by DXA). * $p < 0.05$ and ** $p < 0.001$ when compared to presurgical values. **c, d.** Presurgical PTH and $25OHD_3$ at patients without (white) or with (gray) frailty fractures.

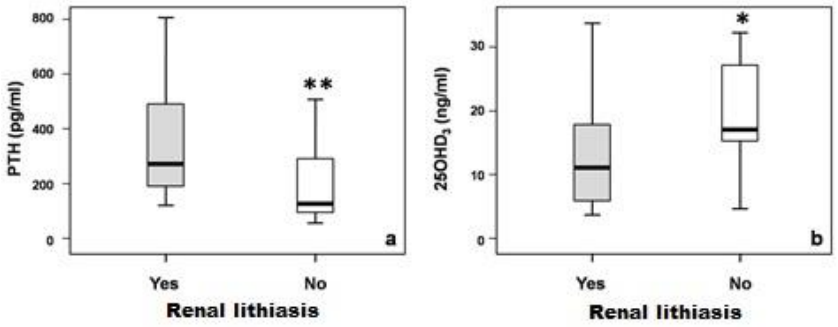

Fig. 4. Mean PTH (**a**) and mean $25OHD_3$ (**b**) in patients with pHPTH with (gray bars) or without (white bars) kidney lithiasis. * $p < 0.05$ and ** $p < 0.001$ when compared with values from patients with lithiasis.

DISCUSSION

We assessed the impact of vitamin D status on the metabolic profile, severity and risk of complications in patients with pHPTH.

We found higher PTH levels in patients younger than 60. Whereas disease incidence is higher at older age, earlier onset may imply increase disease severity, thereby easing a quick diagnosis.

The high incidence of D hypovitaminosis in our patients with pHPTH is striking and may be due to less sunlight exposure and to lack of vitamin D intake (3). After rigorous supplementation, vitamin D levels entered the normal range within one year after surgery. Before surgery, lower vitamin D were associated with higher PTH (p=0.009), fact described by other authors (2,5) and suggesting that hypovitaminosis D may amplify PTH secretion, possibly due to low negative feedback, but could also mask the diagnosis by lowering serum calcium levels (13).

Vitamin D administration in deficient patients is important, but some doctors avoid it in pHPTH before surgery, fearing for an aggravation of hypercalcemia or hypercalciuria. Certain studies (5,8,9) concluded that supplementation of D depleted pHPTH patients before surgery may lower the risk of postsurgical complications, such as hungry bone syndrome. In a 15-year retrospective study Randle et al. (14) suggested that waiting for vitamin D normalization may increase the risk of multiglandular disease and that recurrence, persistence or hypocalcemia were not influenced by the presence or absence of presurgical D hypovitaminosis. Like the previous study, although many of our patients were vitamin D depleted and not substituted before surgery, they did not experience significant hungry bones syndrome after the resection of parathyroid adenomas.

There are also conflicting data regarding bone damage in patients with pHPTH associated with hypovitaminosis D. Whereas several studies (13, 14) described a lower bone mass when hypovitaminosis D coexisted with pHPTH, others (16) found no differences in bone density or microarchitecture despite higher PTH levels.

The patients of our group had overall decreased BMD at all sites before surgery. One year after surgery BMD did not suffer further decrease, and had even a trend to increase at the lumbar spine, as found by others (17), suggesting that the process of bone loss was stopped by the healing of pHPTH. We did not find any differences in

the PTH or vitamin D levels from osteoporotic patients or patients with frailty fractures when compared to patients without osteoporosis or without fractures. Most of our patients had, however, vitamin D levels in a close range of deficiency, severe deficiency or insufficiency; therefore, it would be hazardous to jump to conclusions regarding the impact of low vitamin D levels on bone density in patients with pHPTH.

Renal lithiasis, a classical complication of pHPTH (18), was present in 35.7% of the patients enrolled in the study. The patients with renal lithiasis had significantly higher PTH levels and a significantly more severe D-hypovitaminosis when compared to the patients with pHPTH but no renal lithiasis. To our knowledge, it is the first time when PTH and $25OHD_3$ levels are related to the risk of renal lithiasis in pHPTH. Low $25OHD_3$ may influence lithiasis risk indirectly by favoring the increase of higher PTH levels in pHPTH, as it was recently described (19) in young male patients with relapsing lithiasis and idiopathic hypercalciuria.

CONCLUSIONS

Our study underlined the frequent coexistence between primary hyperparathyroidism and hypovitaminosis D, and how this association may modulate the spectrum of metabolic parameters, thereby influencing disease diagnosis and evolution. Assessment of $25OHD_3$ levels is therefore mandatory in pHPTH. Severe D hypovitaminosis seems to be correlated with larger parathyroid adenomas and higher PTH, possibly influencing the risk of kidney stone formation. It is currently not clear whether D hypovitaminosis contributes to bone frailty or if it increases the risk of postsurgical hungry bones syndrome. Another unanswered question is whether vitamin D reserves should be best repleted before or immediately after surgery.

2-AMINOBENZIMIDAZOLE DERIVATIVES SUPPRESS B-LACTAM RESISTANCE IN *MYCOBACTERIUM SMEGMATIS* AND *M. TUBERCULOSIS*

In a study by Nguyen *et al*, 2-aminobenzimidazole derivatives were tested for the ability to suppress β-lactam resistance in *Mycobacterium smegmatis*. The compounds proved to reverse intrinsic resistance to β-lactam antibiotics of this microorganism. The mechanism of action was different from that of traditional β-lactamase inhibitors. This activity extends to *M. tuberculosis* strains, with suppression of carbenicillin resistance, including in multidrug-resistant strains (Nguyen TV, Blackledge MS, Lindsey EA, Minrovic BM, Ackart DF, Jeon AB, et al. The discovery of 2-aminobenzimidazoles that sensitize *Mycobacterium smegmatis* and *M. tuberculosis* to β-lactam antibiotics in a pattern distinct from β-lactamase inhibitors. CORONARY CIRCULATION AND CARDIAC HEMODYNAMICS – MORPHOFUNCTIONAL AND IMMUNOHISTOCHEMICAL PARTICULARITIES IN PATIENTS WITH ISCHEMIC HEART DISEASE (Abstract): **Aim**: To determine the structural changes and the degree of cardiomyocyte degeneration in relation to coronary circulation and intracardiac hemodynamic indices in patients with ischemic cardiomyopathy (ICM) and ischemic heart disease (IHD). **Material and methods**: 134 patients with circulatory insufficiency NYHA Class I-IV were investigated: 71 with dilated cardiomyopathy (DCM) (mean age 35.6 ± 1.3 years), 17 with ICM (mean age 45 ± 7 years), and 46 with IHD (mean age 54 ± 12 years). Myocardial scintigraphy, CT coronary angiography, ventriculography and morphological and immunohistochemical analysis of sub endomyocardial biopsy were performed. **Results and discussion**: Coronary lesions in patients with ICM/ IHD: 1. circumflex branch - in 86%: grade III stenosis - 31.6%, obstruction in 4.7%. 2. diagonal branch - in 28.0%: grade III stenosis - 100%. LMA - in 62.3%: grade III stenosis - 100%. RCA - in 90.5%: grade III stenosis - 59.2%, obstruction - 40.8%. one-vessel disease - 0.0%; two-vessel disease - 22.7%; three-vessel disease - 28.1%; four-vessel disease - 49.2%. Coincidence of compromised myocardial contractility areas with perfusion defects by combining VRE and rest ^{201}Tl-myocardial scintigraphy was noted in 80% of patients with DCM and in 84.6% of those with ICM / IHD. Hemodynamic indices in patients with ICM and DCM were identical, and in those with IHD, PAP and PTDVS were lower and VTD and IB of VD - higher. Morphologically, cardiomyocytes in a state of apoptotic degeneration were found in all study groups. Immunohistochemically, the apoptotic index (AI) was 13.82 ± 1.66% in the fibrous tissue surrounding area and 2.25 ± 0.86% in areas far from the fibrous portions of the myocardium. **Conclusions**: The severity of cardiac hemodynamic disorders, coronary and intramyocardial circulation in patients with ICM/IHD and DCM directly depends on the nature of morphological and immunohistochemical changes in the myocardium; persistence and similarity of apoptotic process in ICM/IHD and DCM show that apoptosis is the main mechanism of cardiomyocyte death that contributes to the development and progression of heart failure in patients with the above-mentioned diseases. **Keywords**: CARDIOMYOPATHY, APOPTOSIS, CARDIOMYOCYTE, CARDIAC FAILURE.

Mechanisms of development and progression of heart failure depend largely on the ratio of cardiomyocyte death and regeneration. Loss of heart cells occurs main-

ly through apoptosis and necrosis. Involved in cardiomyocyte death are multiple factors, such as Ca^{2+} homeostasis disorder, proteins regulating mitochondrial morphology, ischemia, etc. that have been highlighted in many cardiovascular diseases such as those secondary to ischemia - ICM/IHD and primary myocardial diseases - DCM. In primary myocardial disease, coronary arteries usually show no changes, lumen stenosis and atherosclerotic changes being absent.

In elderly patients, can be detected hemodynamically insignificant atherosclerotic changes of the vessels, and their degree does not reflect the severity of morphological changes of the myocardium.

The small intramyocardial arteries are normal in most cases, but intimal thickening particularly in the areas of cardiosclerosis, increased coronary artery tone, decreased coronary blood flow, reduced degree of coronary artery dilation and therefore decreased coronary reserve can be detected (1). These changes can be related to either to elevated left ventricular end-diastolic pressure (LVEDP) and increased sub endomyocardic and perfusion pressure, or to structural and/or functional changes in the myocardial microvascular bed.

The results with information role in the study of myocardial coronary reserve are obtained by ^{201}TI-scintigraphy using a vasodilator (2). Detection of stable perfusion defects before and after vasodilator administration reveals the presence in those segments of myocardial sclerotic changes or scarring, and their dynamics in one or another direction indicates the perfusion state in the viable myocardium. Based on literature reviews on this topic (3) it can be concluded that the majority of patients with intrinsic myocardial disease present coronary and/or intramyocardial circulation disorders.

Of interest is the comparative study of the possible features of myocardial vascularization, especially at microcirculatory level, intracardiac hemodynamics and cardiomyocyte degeneration in patients with secondary - ICM/IHD and primary myocardial diseases - DCM, of complications of heart failure (HF).

MATERIAL AND METHODS

Our study included 134 patients with circulatory failure NYHA class I-IV: 71 patients with DCM (mean age 35.6 ± 1.3 years), 63 (88.8%) males and 8 (11.2%) females; 17 male patients with ICM (mean age 45 ± 7 years); and 46 male patients with ischemic heart disease (IHD), (mean age 54 ± 12 years).

The used investigation methods were: echocardiography, cardiac catheterization, multi-position coronary angiography, left and right balanced radionuclide ventriculography, sub endomyocardial biopsy with morpho-logical, morphometric and immunohistochemical analysis (TUNEL test).

RESULTS

According to segmentally computerized scintigraphy data, LV myocardial perfusion defects were found in similar frequency in patients with ICM/IHDC (82.5%) and DCM (81.1%), the incidence of perfusion defects occupying over 20% of the left ventricular surface, 45.5% in ICM/IHD and 35.2% in DCM. By combining VRE and rest ^{201}Tl-myocardial scintigraphy, coincidence of compromised myocardial contractility areas with perfusion defects was noted in 84.6% of patients with ICM/IHD and 80% of patients with DCM. Most commonly, in 75% of ICM/IHD cases perfusion

defects coincided with the location of myocardial scarring according to instrumental investigation data (ECG, ECOCG, coronaro ventriculography); in DCM patients, this concordance was found in only 31.8%. Perfusion defect size did not practically differ between patients with ICM/IHD and DCM (tab. I).

TABLE I

Comparison of left ventricular myocardial perfusion defect sizes in patients with ICM/IHD and DCM according to rest ^{201}Tl-myocardial scintigraphy data

	Perfusion defects (% of LV surface)			
	Total per group	**HF I-II (NYHA)**	**HF III-IV (NYHA)**	**p**
DCM	n = 71 13.7 ± 1.3	n = 49 13.1 ± 1.6	n = 22 15.1 ± 2.3	NS
ICM/IHD	n = 63 14.2 ± 1.7	n = 28 9.5 ± 2.0	n = 35 17.7 ± 2.4	< 0.02
Accuracy of p differences	1-3 < 0.002 2-3 < 0.001 1-2 – NS	1-3 < 0.01 2-3 < 0.002 1-2 – NS	NS	

Coronary artery lesions according to coronary angiography data in patients with ICM/IHD consisted in: 1. circumflex branch - in 86%: grade III stenosis - 31.6%, obstruction - 4.7%. 2. diagonal branch - in 28.0%: grade III stenosis - 100%. LMA - in 62.3%: grade III stenosis - 100%. RCA - in 90.5%: grade III stenosis - 59.2%, obstruction - 40.8%. One-vessel disease - 0.0%; two-vessel disease - 22.7%; three-vessel disease - 28.1%; four-vessel disease - 49.2%. All patients with ICM presented right and left ventricular dilatation up to cardiomegaly without cardiac aneurysm formation and left ventricular wall thickening. Optical microscopy revealed in virtually all cases marked endocardial sclerosis progressing to interstitial sclerosis. Also, frequently detected was diffuse-focal myocardial interstitial macro sclerosis. The number of capillaries per surface area unit was greatly reduced. Some cardiomyocytes were vacuolated, and their nuclei were pyknotic. Electron microscopy revealed a significant number of cardiomyocytes in the state of apoptosis. Identification of apoptosis in myocardial biopsy specimens by TUNEL method revealed the presence of immunoreactivity nuclei in all studied patients with DCM, ICM/IHD. The apoptotic index (AI) ranged from 1% to 3% in patients with DCM, and from 1% up to 16% in those with ICM/IHD. In myocardial samples of patients with ICM and high AI (AI = 13.82 ± 1.66%), most apoptotic cells were situated at the periphery of fibrous foci, while in the myocardial segments more distant to these the percentage of apoptotic cells decreased substantially (2.25 ± 0.86%), being identical to the percentage in DCM (2.19 ± 0.82%).

Comparative analysis of hemodynamic parameters and AI% by study group (DCM and ICM/IHD) was made globally in all study patients, taking into consideration only the severity of circulatory insufficiency (tab. II).

When comparing the intracardiac hemodynamic parameters in patients with DCM and ICM with the persistence of

apoptosis process (IA) we have found a direct correlation with left and right ventricle PTD and VTD and an inverse dependence with ejection fraction.

TABLE II

DISCUSSION

Most patients with primary myocardial disease present coronary and/or intramyocardial circulation disorders (3). According to our data, changes in myocardial vascularization at microcirculatory level, intracardiac hemodynamics and immunomorphological degeneration in patients with myocardial diseases secondary to ischemia - ICM/IHD and primary - DCM, and complications of heart failure (HF), are closely related to intimal thickening of small intramyocardial arteries and increased coronary tone, but also to the decrease in coronary blood flow (extraction of ^{201}Tl is increased) and decrease in the degree of coronary artery dilation with reduction of coronary reserve. The above-mentioned changes may be a result of either increased left ventricular end-diastolic pressure (LVEDP) and increased sub endomyocardial and perfusion pressure or of structural and/or functional changes in the myocardial microvascular bed (1). Mechanisms of development and progression of heart failure depend largely on the ratio of cardiomyocyte death and regeneration. Loss of heart cells occurs mainly through apoptosis and necrosis (4, 5, 6). In cardiomyocyte death are involving multiple factors such as interstitial or substitutional fibrosis, metabolic acidosis, Ca^{2+} homeostasis disorder, proteins with a potential of regulating mitochondrial morphology, ischemia etc. and have been highlighted in many cardiovascular diseases such as in those secondary to myocardial ischemia and those associated with primary myocardial disorders (7, 8, 9, 10). The data reported by our study clearly demonstrate both the morphological and functional changes in myocardial vascularization, at all levels, in patients with ICM/DCM, thus confirming the presence in these patients of chronic myocardial hypoxia (ischemia) and its role in primary and/or secondary cardiomyocyte lesions. The immunohistochemical method revealed the presence of immunoreactivity nuclei in

all myocardial biopsy specimens from patients with ICM/IHD - 2.25 ± 0.86% and DCM - 2.19 ± 0.82%. AI index showed a direct correlation with EDP and EDV of the left and right ventricles, and inverse dependence with ejection fraction ($p<0.001$). This demonstrates that excessive myocardial dilation is related to activation of the apoptotic process and desynchronization of myocytes, leading to reduced myocardial contractility and progression of heart failure in patients with ICM/IHD and DCM, thus expanding our knowledge of the pathogenesis of chronic heart failure, and stimulates research and development of measures to prevent circulatory insufficiency in patients with these diseases.

CONCLUSIONS

Our study reveals that the severity of disturbances in cardiac hemodynamics and coronary and intramyocardial circulation in patients with ICM/IHD and DCM is directly dependent on the nature of morphological and immunohistochemical changes of the myocardium; persistence and similarity of apoptotic process in ICM/IHD and DCM show that apoptosis is the main mechanism of cardiomyocyte death that contributes to the development and progression of heart failure in patients with the above mentioned diseases.

MODERN PARACLINICAL EXPLORATION OF RENOVASCULAR ARTERIAL HYPERTENSION (Abstract): Renovascular arterial hypertension (RVAHT) is a type of secondary arterial hypertension (considered the second one in terms of frequency in secondary AHT in adults), which is in a causality relation with a uni- or bilateral stenosis of the renal artery. The concept of RVAHT appeared with Goldblat's experiments (1934), RVAHT being considered a clinical consequence of activation of the renin-angiotensin-aldosterone system. The prevalence of renal artery stenosis (RAS) increases with age, being seen in 7% of the individuals who are over 65 years old. Paraclinical investigations have the role to confirm the clinical suspicion (by objectifying the morphological lesion) and estimate the functional consequences of this lesion. Currently, many of these methods have maintained only their historical value, while in the forefront there are the non-invasive methods which allow a rapid and highly accurate diagnosis. **Keywords:** RENOVASCULAR ARTERIAL HYPERTENSION, RENAL ARTERY STENOSIS, RENIN.

Renovascular arterial hypertension (RVAHT) is a type of secondary arterial hypertension (considered the second one in terms of frequency in secondary AHT in adults), which is in a causality relation with a uni- or bilateral stenosis of the renal artery. The concept of RVAHT appeared with Goldblat's experiments (1934), RVAHT being considered a clinical consequence of activation of the renin-angiotensin-aldosterone system (1-5).

The prevalence of renal artery stenosis (RAS) increases with age, being seen in 7% of the individuals who are over 65 years old. Renal artery stenosis is seen in 20% of the patients with coronary artery disease, 30% of those with aortoiliac disease and 50% of those with peripheral vascular disease. Classically, the accepted pathological criterion is that of "hemodynamically significant stenosis" (1, 2). The positive criterion is the reduction of the diameter by more than 60%, which corresponds to a reduction of the lumen area by about 85%. It is believed that a hemodynamically significant RAS –frequently contributes to the two major complications of the disease: causing renovascular arterial hypertension (RVAHT) and/or altering the renal parenchyma, structurally and functionally, with developing chronic renal failure. It must be remembered that a RAS of over 60% only

sometimes causes RVAHT and more commonly, but not necessarily, it causes renal ischemia with morpho-functional alteration (1, 7).

The causes of RAS can be systematized in the following manner:

1. RENAL ARTERY ATHEROSCLEROSIS (Renal artery stenosis through atheromatous plaque) – is the most common cause, it affects males, it appears in late ages; in this case, the stenosis is in the proximal third of the renal artery, sometimes associated with post-stenotic dilation; it can coexist with other stenosed vascular lesions (carotid lesions, lesions of the lower limb arteries).

2. RENAL ARTERY FIBRODYSPLASIA: it can present itself as medial fibro dysplasia, perimedial fibro dysplasia, intimal fibro dysplasia (more common in children), and subadventitial fibro dysplasia. Fibro dysplasia is more common in early ages, especially in women, and it usually affects 2/3 of the distal area of the renal arteries. They can also be seen in the context of collagen diseases (e.g., Marfan syndrome).

3. RARE CAUSES: renal artery thrombosis and embolism, arterial aneurysm, extrinsic compressions of the renal artery through tumors, arteriovenous fistula, abdominal aorta coarctation, Takayasu's aortitis, renal artery hypoplasia, systemic vasculitis, neurofibromatosis, primary antiphospholipid syndrome, post-irradiation renal artery stenosis, cholesterol crystal micro embolism (1, 3-6, 11, 12).

The pathogenic mechanism of renovascular AHT mainly recognizes the activation of the renin-angiotensin-aldosterone system (experimentally described ever since 1934 by Goldblat), with particularities depending on the uni- or bilateral impairment of the renal artery (and, implicitly from the function of the contralateral kidney) (1, 5, 10).

The diagnosis of renovascular AHT obviously starts from a clinical suspicion which is based on the existence of some suggestive anamnestic or clinical elements. Starting from the criteria of Zanchetti issued in 2001, there are currently several clinical elements which, from a practical point of view, are indicating to the diagnosis of renovascular AHT (1, 11, 12, 14).

They can be represented by one or several of the following elements of clinical suspicion:

- Severe AHT in a child or young adult with no risk factors or after the age of 50 years;
- Severe AHT with onset at any age; onset of grade II severe hypertension (>160/100 mmHg in patients over 55 years old);
- Epigastric, subcostal or flank systolic/diastolic murmur;
- Short-time accelerated evolution of an AHT initially considered essential;
- AHT and inexplicable impairment of renal function;
- Relatively sudden deterioration of renal function in a hypertensive person;
- Refractory AHT in triple drug association;
- Deterioration of renal function as a response to treatment with ACE inhibitor;
- Extensive atherosclerotic lesions of the coronary, cerebral and peripheral arteries in a hypertensive person;
- Recurrent acute pulmonary edema apparently with no obvious cause;
- Lumbar pain with acute onset in the absence of urethral obstruction (1, 4, 5, 7, 9, 11, 12, 14).

Other elements which can orient the clinical suspicion are: the coexistence of

other cardiovascular risk factors: smoking, dyslipidemia, diabetes, worsening of renal failure under antihypertensive treatment, occurrence or worsening of renal failure after arterial catheterization, negative family history for hypertension, severe changes of fundus of eye in a hypertensive person.

There are also biological data which raise the suspicion of renovascular AHT:

- Hypokalemia;
- Hyponatremia;
- Increase of serum creatinine;
- High RA (renin-angiotensin);
- Moderate proteinuria;
- Increase of plasma renin.

Sometimes, a difference of more than 1.5 cm between the longitudinal diameters of the two kidneys in the echography examination, in the context of high BP values, can raise the suspicion of its renovascular etiology (imaging suspicion) (1, 4, 5, 7, 9, 11, 12, 14).

PARACLINICAL INVESTIGATIONS have the role to confirm the clinical suspicion (by objectifying the morphological lesion) and estimate the functional consequences of this lesion.

Currently, many of these methods have maintained only their historical value, while in the forefront there are the non-invasive methods which allow a rapid and highly accurate diagnosis.

Doppler examination of renal arteries combined with renal echography is a non-invasive, cheap method with high sensitivity and specificity, which can reveal the presence of renal artery stenosis (defined as the decrease of more than 60% of the renal artery diameter in the vascular duplex ultrasound) (7, 15 - 17). The method allows the anatomical and functional assessment of the renal arteries. Direct visualization of the main arteries is combined with measurement of the intrarenal pressure and velocity. The main drawback of this procedure is the lack of arterial visualization due to intestinal gases in 50-90% of the cases. At the same time, it allows to determine the resistive index at the level of the renal arteries which is usually high in the hypertensive patient in whom lesions of hypertensive nephron angiosclerosis occurred. The increase of maximum systolic velocity in the renal arteries >180 cm/s and a renal/aortic systolic velocity ratio >3.5 are suggestive of renal artery stenosis. A translesional systolic pressure gradient >15% may represent an indication for angioplasty (15-17). Duplex ultrasound also has a predictive value for the success of renal angioplasty; thus, if the resistive index in intrarenal circulation is higher than 0.8, it is considered that blood pressure will not return to normal after angioplasty in 97% of the patient, and in 80% of the subjects the renal function will not improve (18). However, Zeller et al. (19) have proven in a study on diabetic patients with severe stenosis of the renal arteries at the ostial level that favorable post-angioplasty results can be obtained even if this index exceeds 0.8. The main drawback of this procedure is sometimes the difficult visualization of the arteries due to intestinal gases in 50-90% of the cases.

Renal angiography by nuclear magnetic resonance (with gadolinium) allows the visualization of the renal arteries and accurately tracking renal artery stenosis, it has a high sensitivity and specificity, is non-invasive and potentially non-nephrotoxic. Its drawbacks are related to the need for the patient to maintain apnea during examination and the potential worsening of the results in the case of presence of intracor-

poral metallic bodies (stents, vascular clips, pacemakers) (fig. 1) (20-22).

Spiral computed tomography with CT angiography–entails contrast agent and irradiation of the patient. It has a good sensitivity and specificity for the diagnosis of renal artery stenosis, but it must be avoided in patients with severe chronic renal failure (7, 11, 12).

Selective renal arteriography is the gold standard to confirm the diagnosis. It is currently used in patients with high suspicion of renal artery stenosis in whom non-invasive explorations have been inconclusive. It also allows tracking of accessory renal arteries. The method helps establish the therapeutic indication: thus, concentric, unique critical stenosed (more than 75%) have indication of interventional treatment, while eccentric or multiple stenoses are directed to surgical approach. It has two important risks: nephrotoxicity of the contrast agent and the potential risk of renal atheroembolism. The limits are related to the lack of information regarding renal ischemia and the interdiction of use in significant renal failure (5, 7, 11, 12).

Analyzing 43 clinical cases explored by angiography in the Cardiology Department of " Sf. Spiridon" Hospital, result some practical conclusions. First, renovascular hypertension should be excluded before refractory hypertension is affirmed; 7 patients (16.2%) had this type of blood pressure profile in our analysis. Secondly, secondary hypertension is more frequent in young patients, but the atherosclerotic renovascular hypertension should be taken in account in patients older than 55 years (29 patients in our analysis – 67.4%) with acceleration of a pre-existing essential hypertension (8 patients – 18.6%). Thirdly, although duplex ultrasonography is recommended as the first-line imaging test to establish the diagnosis, the accuracy is operator dependent. When the clinical presentation is highly suggestive, digital subtractions angiography is the key method for both final diagnosis and endovascular treatment. If measuring the translesional pressure gradient to detect a functional artery stenosis is not available, selective bilateral renal vein renin measurement can be useful (19 patients had a significant ratio of 1.8-2) to decide revascularization. 31 of our patients had a successful endovascular revascularization (27 atherosclerotic lesions, 4 fibromuscular dysplasia lesions).

Fig.1. Right renal artery stenosis (collection from the Clinic of Cardiology)

Other methods: Renal isotopic scintigraphy, minuted intravenous urography – are rarely used in present day. Renal scintigraphy (infusion test after captopril) and other radio isotopic methods do not offer anatomic data. On the other hand, by clearly highlighting the infusion asymmetry, scintigram offers predictability data of curing AHT after revascularization, with a sensitivity of 75% and a specificity of 90%.

Scintigram cannot be interpreted in case of bilateral renal artery stenoses and cannot be applied in renal failure. Of the radio isotopic assessment methods of renal flow, those that use technetium-mertiotide or technetium-pentetic acid (DTPA) can determine, quite accurately, the fractional flow for each kidney. This very clearly suggests the possible ischemia, even in conditions of bilateral RAS. In the absence of any morphological information, radio isotopic explorations have not entered the routine practice (7).

The imaging methods will be completed by laboratory data:

- plasma renin activity (PRA) is increased by 50-80%;
- renin-captopril test has a sensitivity and specificity of 75-100%;
- determining plasma renin activity and especially the PRA ratio from the renal vain from the stenotic part and the PRA from the contralateral vein, comparing renin discharge from each kidney; it is useful to predict the success of a surgical revascularization. The increase of renin discharge from the ischemic kidney compared to the health kidney by 1.5 times is considered a positive test (1, 5, 7, 12).

CONCLUSIONS

We confirm that renovascular arterial hypertension continues to remain a challenge for the practitioner physician. The diagnosis is always based on the clinical suspicion and the combination of paraclinical investigations increases the sensitivity and specificity of the diagnosis. Of all methods, selective renal arteriography remains the gold standard of all paraclinical methods to confirm the diagnosis of renal artery stenosis.

NEWS

FATAL TOXIC MYOCARDITIS INDUCED BY PARAPHENYLENE DIAMINE. A CASE REPORT

Para phenyl diamine (PPD) is an aromatic amine derivative of Aniline that is widely used as a cosmetic product, particularly in hair dye preparations. PPD acute poisoning leads to respiratory distress, rhabdomyolysis, muscle necrosis and renal failure. Cardiac complications are rarely reported in the literature. We will present a case of PPD poisoning presenting as myocarditis, associated to rhabdomyolysis with a fatal outcome. The study presented the case of a 22-year-old man who was hospitalized for ingestion of a hair dye. At admission it had a severe edema of the face and neck. Laboratory exams showed renal failure, increased serum lactate deshydrogenase, creatine phosphokinase and troponine T. Toxicological screening showed the presence of Paraphenyl Diamine in blood and stomach. The patient died in the tenth day due to a cardiogenic shock. A forensic autopsy was performed. The pericardium was spotted by multiple hemorrhagic petechiae. The myocardium and the epicardium had multiple hemorrhagic areas. Histological examinations revealed the presence of acute inflammation of the myocardium and epicardium associated with severe ulceration of the endocardium. Inflammatory infiltrate consisted mainly of neutrophils with frequent micro abscesses in the myocardium and epicardium. Death was attributed to Paraphenyl Diamine poisoning complicated with rhabdomyolysis and acute myocarditis. In conclusion, PPD is often used as for suicidal attempt having acute toxic effects such as rhabdomyolysis with renal failure and respiratory distress. There is no specific antidote available in the management of the PPD poisining (Jedidi M, Hadj MD, Masmoudi T, et al. Fatal toxic myocarditis induced by Paraphenylene Diamine. A case report. *Rom J Leg Med* 2016, 24(1): 17-20).

PATHOGENIC FACTORS IN POSTINFECTIOUS IRRITABLE BOWEL SYNDROME-AN UPDATE (Abstract): After acute infectious gastroenteritis, up to thirty percent of patients present prolonged gastrointestinal symptoms and a part of those affected patients can have the diagnostic criteria for postinfectious irritable bowel syndrome. The main diagnosis of a patient with postinfectious irritable bowel syndrome was till this summer, clinically based on Roma III criteria. The Rome IV criteria brought some changes that involve also the postinfectious irritable bowel syndrome, recognizing further the postinfectious IBS as a specific entity according to the multidimensional clinical chronic mucosal inflammation triggered by enteric infection, may underlie persistent bowel symptoms in patients who develop postinfectious irritable bowel syndrome. **Keywords:** GASTROENTERITIS, INTESTINAL INFECTION, POSTINFECTIOUS IRRITABLE BOWEL SYNDROME.

The irritable bowel syndrome (IBS) is an association of chronic and recurrent symptoms such as constipation, diarrhea, bloating and/or abdominal pain, having not any abnormalities (biochemical or structural) detectable by conventional laboratory methods. The irritable bowel syndrome affects 9-13% of the normal population at any particular period in time (1).

Irritable bowel syndrome is defined as recurrent abdominal pain on average at least 1 day a week in the last 3 months associated with two or more of the following: related to defecation, associated with a change in a frequency of stool, associated with a change in form (consistency) of stool. Symptoms must have started at least 6 months ago, according to Rome IV criteria.

The earliest description of postinfectious irritable bowel syndrome (PI-IBS) was made in 1962; Chaudhary and Truelove reported that one third of their patients with a history of gastroenteritis went on to develop irritable bowel syndrome type symptoms (2). Since then, other authors have suggested that patients with an episode of infectious diarrhea have a high incidence of developing irritable bowel syndrome in the following months, with estimates ranging from 4% to 32%. How-

ever, these studies have used varying methodologies, have studied different populations, and a control group was most lacked (3,4,5,6). There are numerous reports, indicating that up to a third of people suffering from bacterial enteritis report persisting ongoing symptoms compatible with irritable bowel syndrome between six months and one year afterwards. Furthermore, though some will recover spontaneous, even at six years, nearly two thirds remain symptomatic (7).

The current conceptual framework regarding the pathogenic mechanisms for postinfectious irritable bowel syndrome suggests that postinfectious irritable bowel syndrome is associated with alteration of motility, increased intestinal permeability, an increased number of enterochromaffin cells and the intestinal inflammation persisted. This was characterized by an increased number of T-lymphocytes and also mast cells and an increased expression of proinflammatory cytokines. This suggests that an exposure to pathogenic organisms that disrupts the intestinal barrier function and alters the neuromuscular function and triggers chronic inflammation, which sustains irritable bowel syndrome symptoms (8).

The postinfectious irritable bowel syndrome is characterized by the sudden onset of symptoms mentioned in the diagnostic criteria for irritable bowel syndrome (with Rome IV criteria being the most recently defined). They appear following an episode of acute infectious gastroenteritis characterized by two or more of the following symptoms and findings: diarrhea, vomiting, fever and a positive stool culture result (9).

Epidemiology. Some studies (10) involving patients ill enough to be hospitalized in an infectious diseases unit, indicate that around 1/3 develop postinfectious irritable bowel syndrome, while other studies dealing with patients in the community have found a lower incidence of around 7% (5) and 9% (11). The net result is that approximately 17% of patients attending general practitioners in the UK attribute their irritable bowel syndrome symptoms to an episode of gastroenteritis (12). The incidence in the USA is much lower, around 6%, though whether this reflects differing referral practice is not certain. Infection is much commoner in the tropics where postinfectious irritable bowel syndrome might be expected to be more frequent though this has not been specifically examined. Certainly, the commonest sub-types of irritable bowel syndrome in Southern India appear to be diarrhea predominant (D-irritable bowel syndrome) (13), while in China D-irritable bowel syndrome also predominates with 65% of irritable bowel syndrome patients fitting this categorization (14). This parallels the findings in a UK study (6).

One of the earliest reports of postinfectious irritable bowel syndrome relates to unexplained diarrhea and abdominal discomfort seen in British troops returning from the World War II North Africa campaign after amebic dysentery (15). A study from Sheffield examined 75 individuals admitted to an infectious disease unit with gastroenteritis, 25% of whom developed new irritable bowel syndrome when assessed 6 months after infection (10).

A further community survey in Nottingham, restricted to just *Campylobacter* gastroenteritis, confirmed a percentage with 9% in a new cohort of 189 infected individuals (11). More recently, there has been a case-control study from Newcastle using Rome II criteria for irritable bowel syndrome, indicating an incidence of new postinfectious irritable bowel syndrome over 6 months of 17% compared with just

1,9% of controls, odds ratio 10 (16). With the exception of the study by Parry *et al* (16) and Ji *at al*.(17), the previous studies lacked a control group to define the normal incidence of new irritable bowel syndrome in the absence of infection. This was corrected in a large study of over 550 000 patients whose records form part of a large general practice research database in the United Kingdom. This database records all interviews with the general practitioner, all prescriptions and all laboratory results. They found 318 patients with documented bacterial enteritis (54% *Campylobacter*, 37% *Salmonella*), 12 of whom had new diagnosis of irritable bowel syndrome over the next 12 months, an incidence of 40 (22-70) (mean 95% confidence intervals)/1000 patients years giving a relative risk of 11.9 when compared with uninfected controls with an incidence of just 3.5/1000 patient years. During a one year follow up, the diagnosis rate of irritable bowel syndrome was 4.4% in patients after an episode of bacterial gastroenteritis (14 subjects), compared with a rate of 0,3% in the general population cohort (2027 subjects). The weakness of this study was that stool cultures are only obtained in around 1 in 10 of all cases of gastroenteritis in the United Kingdom (6). In another cohort study of 295 patients who had recovered from bacillary dysentery (BD) and 243 control subjects (consisting of patient siblings or spouses who had not been infected with BD) is investigated the incidence of irritable bowel syndrome and FBD (functional bowel disorders) in a Chinese patient population (in Beijing). All subjects were followed up using questionnaires for 1-2 years to explore the incidence of FBD and irritable bowel syndrome, as defined by the Rome II criteria. In the BD infected cohort, the incidences of FBD and irritable bowel syndrome were 22.4% and 8.1% (in total)-10.2% (among those in who *Shigella* were identified) respectively, which were significantly higher ($p< 0.01$) than the incidences of FBD (7.4%) and irritable bowel syndrome (0.8%) in the control cohort (18). While irritable bowel syndrome is common in western societies such as the USA or UK, early studies suggest that in developing countries, the prevalence is low (1). Irritable bowel syndrome was considered by Henry Bockus to be the most valid example of a civilization disorder (19). It is speculated that low prevalence of irritable bowel syndrome in underdeveloped countries is determined by an increased exposure to infection during the child age, rather than to fiber reach meals. The colonization of the intestine by micro flora and also the development of broad immune tolerance can result from the exposure to a variety of microorganisms early in life and enables the intestinal epithelium to respond more efficiently to antigenic challenge, during an episode of gastroenteritis. This leads to symptoms that resolve more quickly. In area with better hygienic conditions, the immune system of the gut is preserved naïve to exposures. Having episodes of gastroenteritis in later life can cause inflammatory disturbances. This, but also behavioral and psychological factors, predisposes to the persistence of symptoms suggestive for irritable bowel syndrome (1).

Gastroenteritis due to viral etiology is mostly associated with acute episodes of diarrhea and little residual injury. This might be associated with a lower incidence of postinfectious irritable bowel syndrome, in comparison with infection due to bacterial pathogens. In an outbreak of presumed viral gastroenteritis, one quarter of the patients developing gastroenteritis reported symptoms of postinfectious irritable bowel syn-

drome at 3 months after the outbreak (8). Consistent among these studies is the suggestion that postinfectious irritable bowel syndrome is different for any ethnic group or environment and became a global phenomenon. The prevalence or incidence of postinfectious irritable bowel syndrome varies in part because of differences in study methodology, including the criteria used to define irritable bowel syndrome. In general, Rome II criteria generate lower estimates than Rome I or III. Postinfectious irritable bowel syndrome has a defined moment of onset in comparison with sporadic irritable bowel syndrome. Features of the inciting infectious illness such as diarrhea, abdominal cramps, increased stool frequency, bloody or mucous stools, and positive stool culture and weight loss are potent predictors of long term outcome. The risk of postinfectious irritable bowel syndrome appears to correlate with the severity of the acute enteric infection, increasing at least two-fold if diarrhea lasts more than 1 week and over threefold if diarrhea lasts more than 3 weeks. Bloody stools, abdominal cramps and weight loss are also associated with high risk, with abdominal cramps increasing the risk fourfold (8).

Pathogenic mechanisms. Prospective studies provide strong evidence that the development of postinfectious irritable bowel syndrome involves an interactive multifactorial etiopathogenic process. Psychological factors: like hypochondriasis, an important life event stress preceding the infectious episode were strong predictors for the developing of irritable bowel syndrome. Increased expression of interleukin 1 β m RNA present in rectal biopsies and increased numbers of intraepithelial lymphocytes and T- lymphocytes in rectosigmoid biopsies suggest that the pathogenesis of postinfectious irritable bowel syndrome is also sustained by an inflammatory process. Possible other mediators include TNF-α and interferon-γ. Inflammation is usually associated with activation of cyclo-oxygenase 2 (COX-2) enzymes and an associated rise in prostaglandins, which sensitive visceral afferents and stimulate secretion and intestinal propulsion (20). The other striking abnormality was an increase in entero-endocrine cells which may explain an increased serotonin release by test meal which others have reported (21).

In animal models inflammation can induce entero-endocrine cell hyperplasia and increase serotonin release but the effects on bowel motility are unpredictable since in this model there was receptor desensitization and impaired peristalsis (22).

A study from China regarding postinfectious irritable bowel syndrome observed a similar increase in the inflammatory markers above mentioned. They also discovered the numbers of mast cells in terminal ileum biopsies of both postinfectious irritable bowel syndrome as well as non-postinfectious irritable bowel syndrome patients were increased compared with controls. Another study from New Zealand discovered high levels of mast cells in colonic biopsies taken from patients with irritable bowel syndrome with non-specific microscopic inflammation on conventional histology. The particularity in this study was the finding of immune activation in a group of irritable bowel syndrome patients whose presentation was atypical for postinfectious irritable bowel syndrome. These patients had more chronic irritable bowel syndrome symptoms, with an insidious onset and their colonic biopsies were judged to be normal on conventional histology.

Role of inflammation in irritable bowel syndrome. Epidemiological studies sug-

gest an association between inflammation following prior infection and the persistence of irritable bowel syndrome symptoms. The interdependence of prior infection and psychological status has also been consistently documented (22), and this may question the role of persistent inflammation as an independent risk factor. The data are interpreted as evidence of the importance of psychoneuroimmune interactions; it is unclear whether the inflammation is a key common final pathway to non-specific psychological influence on intestinal function, and the prior infection potentially unrelated other than as an initiator of the cascade of events. A summary of the epidemiology data also shows that the prevalence of PI- irritable bowel syndrome is no more prevalent than irritable bowel syndrome in the general population. A second approach is to review the quantitative differences in the inflammation and their association with symptoms. Many studies have documented increased numbers of CD3, CD25 or mast cells in ileal, colonic or rectal biopsies, but the differences for lymphocyte counts between controls and irritable bowel syndrome are small, with predominant overlaps in the counts between the two conditions (24). The third line of evidence to be examined is the response to anti-inflammatory treatment of irritable bowel syndrome. A controlled trial has shown that, among carefully selected patients with postinfectious irritable bowel syndrome, prednisone 30 mg b.i.d. was not significantly better than placebo and while placebo resulted in the customary, no change in score was noted in the prednisone treatment group, significant 30% change in median symptom score relative to baseline (25).

Prognosis. Like other types of irritable bowel syndrome, symptoms in postinfectious irritable bowel syndrome fluctuate but are generally chronic. Spiller found only 43% had recovered at six years which was not significantly different from the 31% of those with pre-existing irritable bowel syndrome (26).

Hypothesis on the cause of increasing irritable bowel syndrome prevalence in developing countries. It is speculated that low prevalence of irritable bowel syndrome in underdeveloped countries is determined by a high childhood exposure to infection, rather than high residue diet. The microflora colonization of the intestine and the development of broad immune tolerance can result from the exposure to a variety of microorganisms early in life and enables the intestinal epithelium to respond more efficiently to antigenic stimulation leading to symptoms that resolve more quickly, during an episode of gastroenteritis. On the other hand, the intestinal immune system remains relatively naive in the more hygienic environment associated with improved socioeconomic conditions. Acquiring acute gastroenteritis later in the life results in inflammatory changes. This factor together other factors, i.e. with psychological and behavioral factors, predisposes to the persistence of symptoms manifesting as irritable bowel syndrome (1).

Postinfectious IBS in Rome IV era. The Rome IV criteria bring (27) some new approaches in the field of functional gastrointestinal disorders and specifically in IBS (28). The pain remains the main feature of IBS diagnosis and frequency of pathological stools have major importance in subtyping IBS following the presentation of the stools according to the Bristol scale. The postinfectious entity is further acknowledged. Its definition changed together with the definition of the IBS as a category, not specifically because of the infectious trigger. However the infectious trigger has to

be mentioned according to the multidimensional clinical (29).

CONCLUSIONS

Our conclusion is that Rome IV recognize further the postinfectious IBS as a specific entity, according to the multidimensional clinical chronic mucosal inflammation triggered by enteric infection may underlie persistent bowel symptoms in patients who develop postinfectious irritable bowel syndrome.

HYDROGEN PEROXIDE VASORELAXATION INVOLVES S-GLUTATHIONYLATION OF VOLTAGE-DEPENDENT K CHANNELS

H_2O_2 is an endothelium-derived hyperpolarizing factor (EDHF), but H_2O_2 effects vary with the vascular bed and experimental conditions. If H_2O_2 relaxes rat mesenteric artery, what is the mechanism? Methods: myography of isolated resistance arteries, patch clamp of mesenteric arterial smooth muscle cells (MASMCs), streptavidin pull-down assays with biotinylated glutathione ethyl ester. Relaxation of precontracted arteries by H_2O_2 was reversed by dithiothreitol, reduced by 4-aminopyridine (4-AP), blocker of voltage-dependent K channels (K_v) channels, but not by blockers of big-conductance Ca^{2+}-activated K^+ channels or of inward rectifier K^+ channels. H_2O_2 increased K_v currents; this was prevented by glutathione reductase; K_v incorporates glutathione (GSH) in the presence of H_2O_2. Thus, H_2O_2 activates Kv channels (maybe via S-glutathionylation) with artery relaxation, while the basal redox status of MASMCs determines K_v response to H_2O_2. (Park SW, Noh HJ, Sung DJ et al. Hydrogen peroxide induces vasorelaxation by enhancing 4-aminopyridine-sensitive Kv currents through S-glutathionylation. *Pflugers Arch* 2015; 467(2), 285-297).

POTENTIAL NEW ROLES OF LEPTIN IN HEALTH AND DISEASE (Abstract). Leptin is an adipose-tissue specific cytokine described 20 years ago and classically thought to be involved in regulation of food intake and energy homeostasis. More recently, leptin was proven to exert other multiple roles in carbohydrate and lipid metabolism, reproductive system, and inflammatory and immune reactions. Emerging data propose leptin to be a modulator of bone mass. In some particular circumstances leptin synthesis follow specific patterns in inflammation and sepsis, not being proportional with fat mass. Therefore, it may be used as diagnostic or prognostic marker for critical illness. **Keywords:** LEPTIN, ADIPOSE TISSUE, BONE MASS, CRITICAL ILLNESS.

The adipose tissue has the capacity to respond to afferent signals and synthesizes efferent signals, contributing to cross-communication between organs and tissues (1,2). Certain molecules synthesized by adipose cells play the role of hormones, being called adipokines, and are known to act locally and systemically on specific receptors (1-3). Both adipose tissue excess and severe deficiency alter the adipokine profile (1). Excessive fat may have a deleterious metabolic impact, contributing to harmful consequences, such as hyperglycemia, insulin resistance, dyslipidemia, and the increased cardiovascular risk that accompany obesity (4). Leptin (name derived from the greek *leptos*, meaning thin) is a hormone mainly synthesized by subcutaneous white adipose cells (2), firstly described in mice more than 20 years ago (5). Defects in leptin synthesis were associated with extreme obesity in ob/ob mice, indicating the hormone as being an important regulator of appetite and fat mass accumulation (6). The human leptin equivalent is a 16 kDa protein (7), acting on target cells through at least six isoforms of plasma membrane receptors and signaling predominantly via the Jak-STAT pathway (6-8). Many leptin receptors are expressed in the brain, especially in the hypothalamus (6), suggesting that the hormone may act on the inhibition of appetite via central effects (2,6.8). Leptin was proven in animal models to regulate satiety, energy homeostasis and body weight through three leptin sensitive neurons found within the hypothalamic arcuate nucleus: neuropeptide Y (NPY), gamma aminobutiric acid (GABA) and proopiomelanocortin (POMC) neurons, the

first two, with an orexigenic role, being inhibited and the third, anorexigenic, being stimulated by the hormone (2). Leptin also affects adipose tissue through autocrine effects on adipocytes, directly increasing energy expenditure (2,9). Initial hopes to find an ideal "slimming hormone" were deceiving: leptin administration has no effects on weight in the vast majority of obese patients (2,10,11). Newer studies used combinations of leptin with other agents that increase the responsiveness to leptin, such as amylin analogues, and showed initially promising weight loss, but the subsequent development of autoantibodies, impeded further beneficial effects (12). The reason why leptin therapy is inefficient in the overwhelming majority of obese patients is that obesity represents most frequently a chronic state of energy excess (13). Obese individuals usually have elevated adipose leptin expression and plasma leptin levels, proportional to fat mass, but these high leptin levels fail to reduce hyperphagia and adiposity excess, indicating a state of resistance to both endogenous and exogenous leptin (14). On the basis of studies conducted mainly in rodent models, leptin resistance has been attributed to multiple factors, including impaired leptin transport across the blood-brain barrier, and a disruption of leptin signaling in target cells (15). An absolute minority of extremely obese patients has a proven defect in leptin synthesis or receptivity and the rare leptin deficient obese patients do benefit from leptin therapy (16). These particular conditions are direct proof of the important leptin involvement in fat tissue homeostasis. It is known that obese children are taller, but their puberty starts at an earlier age. The reach of a certain critical mass of adipose tissue may be an important puberty trigger, and leptin secretion may also play a role in puberty onset (17). Leptin, as well as other adipokines, have other metabolic effects including lipid oxidation, energy utilization, modulation of insulin activity, effects on bone metabolism and an inflammatory role (2-4).

LEPTIN AND BONE

Leptin is presently considered to be a mediator between adipocyte and bone metabolism (18). Leptin receptors were described on osteoblasts, in vitro and in vivo effects of leptin on bone metabolism are multiple and frequently antagonistic (18,19). It is shown that leptin stimulates bone formation through a direct mechanism, but inhibits the recruitment of osteoclastic precursors, thereby decreasing osteolysis (18). However, its central effect of stimulating the sympathetic nervous system causes bone demineralization in animal models (19). The role of leptin on bone mass acquisition in humans is presently not fully comprehended. Buta, Branisteanu et al. observed that leptin was an independent predictor of bone mass at postmenopausal women (Fig. 1) (20).

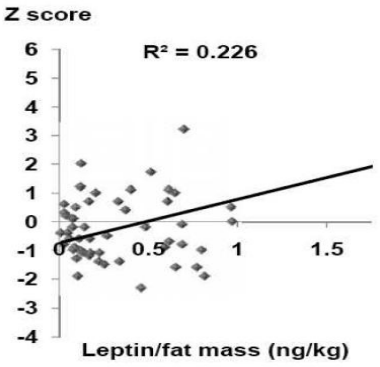

Fig 1. Positive correlation of serum leptin normalized to fat tissue mass with the Z score at postmenopausal women ($p < 0.05$)

LEPTIN AND INFLAMMATION

Leptin has a structural similarity to various cytokines. Moreover, leptin-specific receptors belong to the class I cytokine receptors and are found on immune cells such as monocytes, lymphocytes and neutrophils (2). Leptin may therefore exert significant immune modulating effects. Many obese people present, indeed, a chronic inflammatory condition. This obesity related immune reactivity is attributed to the high leptin levels, which may activate macrophage phagocytosis and T-helper 1 mediated responses, through the synthesis of other proinflammatory cytokines, such as IL-2, IL-6, IFN-gamma or TNF-alpha (21). Taking into consideration the above mentioned data, leptin may be regarded as an adipose cell-synthesized proinflammatory cytokine (22,23).

LEPTIN AND CRITICAL ILNESS

Critical illness represents an extreme stress adaptation caused by a multitude of triggers (24). This adaptation includes important acute immune reactions in the frame of a systemic inflammatory immune response (SIRS), seemingly different in aseptic and septic circumstances (25). The immune system is influenced by the adipose tissue through adipokines such as adiponectin and leptin, therefore SIRS and sepsis are expected to be accompanied by changes of these cytokines (26-28). SIRS or sepsis related leptin level changes may therefore be used as a diagnosis and prognosis marker (29). The role of leptin during critical illness is difficult to be established due to contradicting clinical and experimental data (29-36). These differences may originate in the timing of blood sampling and the different types of critical conditions. Grigoras et al. evaluated for the first time early (first 24 hours) leptin variations in critically ill patients with SIRS or sepsis (29). They observed different leptin dynamics: a steep early leptin increase in SIRS, but a flat answer in sepsis (Fig. 2). The two different early evolution patterns of leptin dynamics may indicate the presence or absence of infection and mandate for the early institution of antibiotherapy, if needed (29).

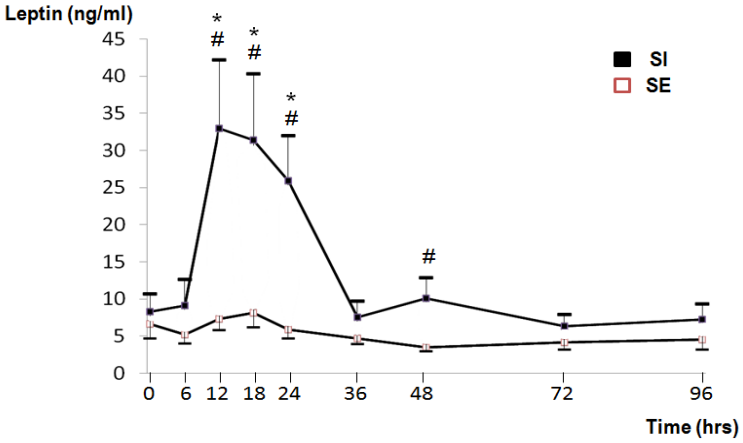

Fig 2. Temporal dynamics of leptin plasma levels in the SIRS group (SI, black rectangles) and in the SEPSIS group (SE, white rectangles). Data are represented as means ± standard deviation. # $p < 0.05$ compared to SE; * $p < 0.05$ compared to initial value.

Moreover, the authors observed that mortality risk of septic patients is higher at low leptin and high IL-6 levels (Fig. 3). Adipose tissue may therefore, via adipokine secretion, play a protective role during sepsis and critical illness in overweight and obese patients (the so called "obesity paradox"), by the capacity to provide energy stores, to spare muscle wasting and to regulate the immune response (29, 37).

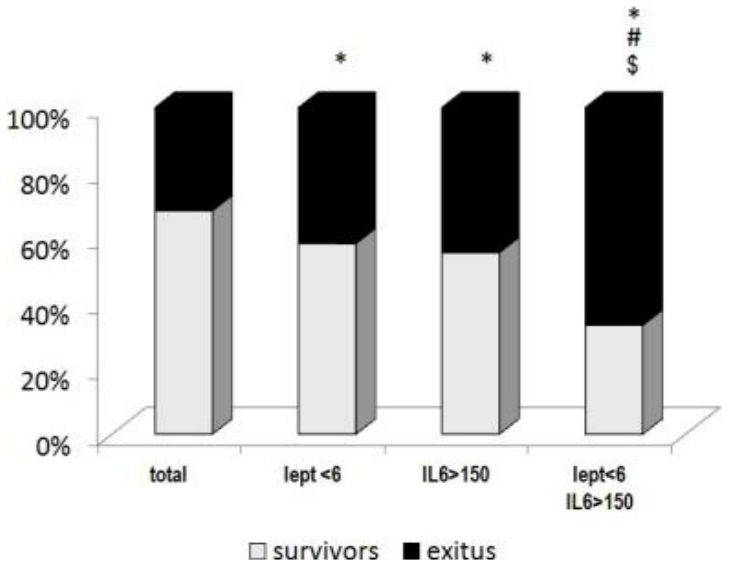

Fig 3. Mortality incidence among patients in critical state with sepsis – whole group (total), patients with leptin < 6 ng/ml, patients with IL6>150 pg/ml and patients with both leptin < 6 ng/ml and IL6>150 pg/ml at the onset of the follow up. Patients with both modified parameters had highest mortality. * $p<0.05$ compared to mortality in the whole group, # compared to mortality in the group with leptin < 6 ng/ml, $ compared to mortality in the group with IL6 > 150 pg/ml (square chi test).

CONCLUSIONS

Leptin, the adipokine originally described as having a crucial role for adipose tissue balance, is presently known to be involved in the interplay between various body compartments. Leptin may play a direct effect on bone mass acquisition and is involved in inflammatory reactions. The critical illness associated inflammation is accompanied by specific leptin level changes, that may be used as diagnosis and prognosis markers in critically ill patients.

ATOPIC DERMATITIS - CLINICAL EPIDEMIOLOGY AND IMMUNOLOGICAL CORRELATIONS (Abstract) **Aim:** Medical records from 2010-2014 were retrospectively reviewed and analyzed in view of determining the correlations between the clinical severity of atopic dermatitis (AD) and total IgE level, eosinophilia, place of residence, family history of atopy, type of birth, and natural or artificial feeding. **Material and Methods**: Following medical record review, 296 cases diagnosed with AD were included in the study. Statistical analysis was performed using SPSS v20 for determining the frequency and testing the hypotheses, for $p < 0.05$, by t tests and One-Way ANOVA. **Results:** Of the 296 cases, 53% were male children and 47% female children aged 1 month to 16 years. According to total serum IgE level, 49.3% of patients had elevated IgE levels, 20.6% normal levels and in 30.03% of cases it was not determined. According to the SCORAD, children had mild AD in 20% of cases, moderate in 70%, and severe in 10%. The independent samples t tests showed a statistically significant difference between the means demonstrating correlations between IgE level and place of residence ($p < 0.01$), family history of atopy ($p < 0.01$), baby feeding ($p < 0.01$), and by one-way ANOVA for SCORAD ($p < 0.05$). **Conclusions:** Atopy in AD can be influenced by complex factors, both internal and environmental, but this remains a controversial topic. External factors acting on a background genetically predisposed to atopy trigger the manifestation of AD. **Keywords:** ATOPIC DERMATITIS, FOOD ALLERGIES, FAMILY AGGREGATION, ENVIRONMENTAL FACTORS.

Atopic dermatitis (AD) is a chronic inflammatory skin condition characterized by intense itching. In 2003, the European Academy of Allergology and Clinical Immunology revised nomenclature of allergic diseases and proposed the term atopic eczema for the Immunoglobulin E-mediated skin inflammatory disorder occurring in genetically predisposed individuals (1, 2).

Atopic eczema develops in early childhood. About one in five school-age children have atopic eczema. Quality of life is altered as it affects sleep and concentration, school attendance, and self-image. AD starts at ~ 2 months (90% before the age of 5 years). Prevalence is 10-25% in the US, Northwestern Europe, and Australia (3).

In the etiopathogenesis of AD are involved the following factors: genetic predisposition, family aggregation, low expo-

sure to infectious agents and/or commensal microbiota - hygiene hypothesis and rise in living standards - "Western lifestyle" (4).

The genetic risk factor is represented by loss-of-function mutations in the filaggrin gene (FLG), an important epidermal barrier protein and precursor of natural moisturizing factor, involved in epidermal integrity (3,4).

Seventy percent of the patients with AD have a family history of atopy. If both parents are atopic their children have an 81% risk for developing atopy; when one parent is atopic and the other parent is non-atopic the risk is of 56%; frequency of atopic manifestations in other family members (first-degree relatives) is associated with a 28% risk (5).

Among the factors that could favor the onset and progression of AD lesions, the most commonly incriminated are: dietary factors - cow milk, eggs, peanuts, nuts, soy, wheat, fish, seafood, airborne allergens, infectious agents - *Staphylococcus aureus*, *Pytirosporum ovale*, contact factors - cleaning agents, astringent solutions, perfumes, harsh soaps and detergents, tight and abrasive clothing and physical factors - extreme temperatures, emotional stress (6).

MATERIAL AND METHODS

This retrospective study analyzed the data collected from medical records from 2010 - 2014. There were 296 cases of AD of which 53.05% were male and 46.95% female children from all Moldavian regions. Distribution of cases by county of residence was the following: 73.99% Iasi county, 8.44% Neamt county, 4.72% Botosani and Vaslui counties, 4.05% Suceava county, and 0.67% Vrancea and Galati counties.

The diagnosis of AD was made according to Haniffin and Rajka criteria, and the severity of lesions was based on SCORAD score calculation according to the international protocol and classified as mild (<15), moderate (15-40) and severe form > 40 (7).

Inclusion criteria were patients at first presentation to our clinic with or without a personal history of AD. The following data were analyzed: gender, place of residence (rural or urban), family history, personal history (type of delivery and feeding), previous medical history (recurrent allergic reactions and respiratory infections), SCORAD, total IgE and specific IgE levels.

Statistical analysis was performed using SPSS v20 for determining the frequency and testing the hypotheses, for $p < 0.05$.

RESULTS

Of the 296 AD cases 37.5% were recorded in 2014, 19.26% in 2010, 17.22% in 2013, 13.18% in 2011 and 12.84% in 2012 (fig. 1). Fifty-three percent of the children were male and 47% female, aged from 1 month to 16 years. An incidence of 30.3% in the first 6 months of life and of 80.8% in the first 3 years was found (fig. 2), values close to those reported in the literature (7).

These patients were diagnosed according to Haniffin and Rajka criteria corroborated with the clinical and laboratory findings at the first admission (8). Thus, total serum IgE level was elevated in 49.32% of patients, normal in 20.61% of patients, and in 30.07% it had not been determined. Studies report a higher frequency of AD in urban than in rural areas (9, 10, 11). In our study, 52% were urban patients and 48% rural patients, average of 1.52, SD = 0.50 (standard deviation) and variance of 0.250. The independent samples t-test showed that for $t(294) = -0.98$, the p value was greater than 0.01 but F test rejected the null hypothesis, therefore the place of residence influences AD (tab. I).

	df		294	281,978
	Sig. (2-tailed)		,328	,330
	Mean Difference		-,099	-,099
	Std. Error Difference		,101	,102
	95% Confidence Interval of the Difference	Lower	-,299	-,300
		Upper	,100	,101

Babies born by cesarean section are not more likely to develop AD compared to those born naturally (9, 10, 11, 12, 13). In our study, 65.9% of children were born naturally and 34.1% by caesarean section, average of 1.34 and SD = 0.47. T test, bivariate correlation it-s not statistical significant to support the hypothesis that cesarean delivery increases the risk for developing atopy for t (294) = - 0.780, p> 0.05, and F test did not reject the null hypothesis.

The frequency of food-allergy among infants and young children, which contributes to worsening of AD lesions is of approximately 20-40%. Early feeding with powdered or cow milk, early introduction of allergenic foods such as fish, egg, peanuts, in the diet of both breastfeeding mother and infant can aggravate AD lesions (6, 14, 15).

In our study group we could see how the introduction of artificial feeding with milk powder or cow milk during infancy causes shortly after the occurrence of AD lesions. Artificially fed were 76% of children and 24% were breastfed, with a mean of 1.76 and SD = 0.42. 52.36% of cases were clinically diagnosed with cow milk protein allergy, children aged 1 month to 3 years. Determination of specific IgEs revealed: 6.08% of cases with positive specific IgE to milk, 2.36% to house dust mites, 1.68% each to egg, peanuts and animal hair and epithelia (dog, cat), 1.01% to nuts, soy, potato, fish, fruits, chocolate, and grasses. Upper gastrointestinal endoscopy was performed in one case and found eosinophilic esophagitis.

To determine if nutrition affects AD t test was used. For t (294) = 1.30 we obtained a p> 0.05 which is not statistically significant, but F test rejected the null hypothesis (tab. II).

TABLE II

Independent samples t test to compare the averages for the type of food and IgE

			Immunoglobuline E	
			Equal variances assumed	Equal variances not assumed
Levene's Test for Equality of Variances	F		10,997	
	Sig.		,001	
t-test for Equality of Means	t		1,302	1,415
	df		294	136,056
	Sig. (2-tailed)		,194	,159
	Mean Difference		,154	,154
	Std. Error Difference		,118	,109
	95% Confidence Interval of the Difference	Lower	-,079	-,061
		Upper	,387	,370

When comparing the feeding and SCORAD means, p was greater than 0.05 and no correlation between them was found.

The estimation of borderline IgE means showed a stronger correlation between artificial feeding and natural delivery, but feeding and natural delivery also influence atopy to a certain degree (fig. 3).

Family aggregation has been studied from the viewpoint of a family history of asthma, allergic rhinitis, atopic dermatitis and urticaria. In 82.77% of our cases we found the absence of allergies; allergies were present in 14.53% in one parent, grandparent or sibling

and in 2.70% in both parents or a sibling and a parent, with an average of 0.20, variance of 0.21 and SD = 0.46.

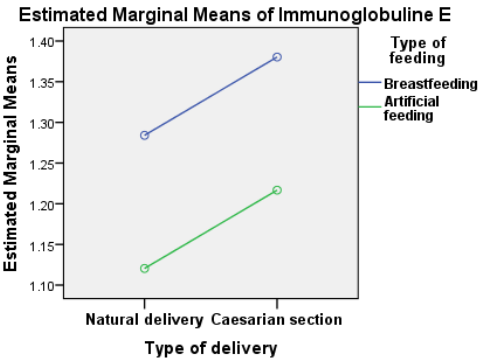

Fig. 3 Correlation between IgE feeding and type of delivery

The use of bivariate analysis showed statistically significant values for IgE, p <0.01, t test for comparing means was statistically insignificant for t (49) = 1.34, p> 0.05, the null hypothesis being rejected by F test which is statistically significant at p <0.01 (tab. III). One-way ANOVA of the means showed difference only between the means for both parents allergic and a brother and one parent allergic without family history of allergies, 1.75 and 1.15, respectively. The difference was not statistically significant because p> 0.05. Multiple comparison revealed no statistically significant differences as p> 0.05, even if the difference between the means was negative.

TABLE III

Independent Samples t Test to compare averages between IgE and familial history of allergy

			Immunoglobuline E	
			Equal variances assumed	Equal variances not assumed
Levene's Test for Equality of Variances	F		10,301	
	Sig.		,002	
t-test for Equality of Means	t		-1,344	-2,019
	df		49	17,803
	Sig. (2-tailed)		,185	,059
	Mean Difference		-,424	-,424
	Std. Error Difference		,316	,210
	95% Confidence Interval of the Difference	Lower	-1,059	-,866
		Upper	,210	,018

According to AD severity score, 19.94% of the children had a mild form of disease, 69.59% moderate and 10.47% severe, with an average of 2.00, SD = 0.54 and variance of 0.29.

Bivariate correlation of the means showed a strong association between IgE level and the degree of AD lesions severity for p <0.01. One-way ANOVA revealed statistically significant means differences between patients with mild and severe disease according to SCORAD index - 0.93 versus 1.35, at multiple comparison the difference of means being significant for p <0.05 (tab. IV). Also the graphical representation of means shows the correlation between SCORAD score and IgE level (fig. 4).

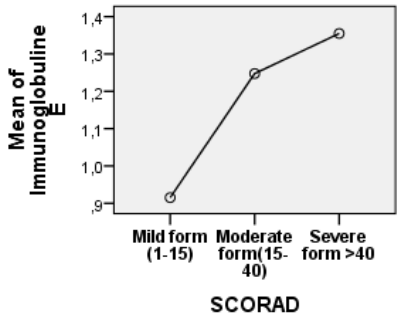

Fig. 4 Graphic representation of IgE and SCORAD means

Skin barrier impairment facilitates superinfections, especially by *Staphylococcus aureus*, *Streptococcus pyogenes*, *Herpes simplex*, *Molluscum contagiosum*. It preserves skin inflammation with further persistence of lesions (10, 17, 18). In our study skin superinfection was found in the severe forms of DA. Thus, 9 of the 31 children with severe SCORAD score presented superinfection by *S. aureus*. Of these children one each associated *Haemophilus influenzae*, *E. coli*, *P. aeruginosa*. Other colonizations: one child by *Streptococcus pyogenes* and one child by *Enterobacter spp* and *Enterococcus faecalis*.

DISCUSSIONS

The epidemiology of AD is important for identifying the risk factors that can be acted upon, it being a dynamic disease influenced by environmental and genetic factors. It is common in infants and small children. This study on AD ethiopathogenesis was in agreement with other similar studies by the incidence close to that in the literature and the onset most frequently occurring in infancy at the age of 2 months (10). Gender distribution was equal.

The place of residence influences the development of AD, with a higher risk in urban areas in developed countries (9, 10, 11). Given the small difference between urban and rural patients in our study, it is more likely that other factors influence the development of AD, such as processed foods or genetic background.

In our study delivery type did not increase the risk of developing AD, but some studies confirmed high birth weight and prematurity by impaired skin barrier function as risk factors (11).

Food allergies are common among patients with AD. Given the age of onset, feeding plays an important role. Breastfeeding is a protective factor against many illnesses. In AD this hypothesis is not supported by studies, as there may be variations in breast milk composition or in other factors that may influence breastfeeding. Thus, in our study the means for IgE, diet type delivery type showed that feeding and natural birth can influence atopy (6, 14, 15). Additional administration of hydrolyzed cow milk formulas and probiotic supplementation may have a beneficial effect in preventing disease development in high-risk children not exclusively breastfed (5, 10, 11, 14, 15).

The well-known risk factors that are strongly correlated with the development of DA are family history of atopy and filaggrin loss-of-function mutations. In our study we found that family history of atopy is statistical significant (11).

As currently there is no specific biological marker that differentiates between AD and other allergic diseases, the diagnosis of DA is clinical, based on history, morphology and distribution of skin lesions, and associated clinical signs (8, 10). The most common laboratory finding in AD is an elevated total IgE and/or specific IgE level. According to IgE level, researchers classified AD into two groups of disease: intrinsic and extrinsic. In our study the extrinsic group type was prevalent. Inflammatory and cytokine profile differentiate between acute onset and chronic forms. These forms are controversial because the individual with AD can later develop elevated IgE levels and specific IgE positivity as a secondary phenomenon. Moreover, although statistically the severity of AD correlates with elevated IgE levels, this does not mean that in all forms of severe AD IgE level is elevated (10, 11, 16, 18).

CONCLUSIONS

The rise in the number of AD cases requires a more thorough analysis of the way environmental factors interact with predisposition of the child to atopy.

In this case feeding and lifestyle influence the child since infancy.

Discovering the cause of this condition to reduce disease severity is difficult in many cases.

NEWS

HORMONAL CONTRACEPTIVES, GENITAL TRACT INFECTIONS AND HIV RISK

The hormonal contraceptives and genital tract infections are associated with altered cervical immunity. A recent study that evaluated changes in cervical immunity after taking hormonal contraceptives showed that the women who used injectable depot medroxyprogesterone acetate and those who use estrogen-progesterone oral contraceptives had increased levels of proteins that attract HIV host cells. Also, the effect of hormonal contraceptives was exacerbated in presence of disturbed vaginal microbiota or genital tract infections such as gonorrhea, chlamydia, genital herpes, trichomoniasis and candidiasis. The levels and the type of immune mediators, infection status and hormonal contraceptives increase HIV risk by their cumulative action. (Fichorova RN, Chen P-L, Morrison CS, Doncel GF, Mendonca K, Kwok C, Chipato T, Salata R, Mauck C. 2015. The contribution of cervicovaginal infections to the immunomodulatory effects of hormonal contraception. *mBio* 6(5):e00221-15. doi:10.1128/mBio.00221-15).

Clinical Hospital of Infectious Diseases "Sf. Parascheva" Iasi

CHARACTERISTICS OF HEPATITIS B VIRUS COINFECTION AMONG HIV-INFECTED PREGNANT WOMEN (Abstract)The similar routes of transmission for HIV and HBV place patients with either infection at greater risk for HIV/HBV co-infection.Aim: To determine the particularities of hepatitis B virus (HBV) coinfection in pregnant women infected with human immunodeficiency virus (HIV) and its influence on pregnancy. Methods: Retrospective study of 74 HIV-infected women monitored during pregnancy in the Iasi Regional HIV/AIDS Center (Romania) from 2010 to 2013. The subjects were divided into 2 groups according to the presence or absence of HBV coinfection. Results: Most subjects belonged to age group 20-24 years (90% in the HIV group *versus* 75.5% in the HIV/HBV-coinfected group). HIV infection was most commonly transmitted by parenteral route (65.5 % *vs.* 48.9 %). The majority of patients were married (60 % *vs.* 65 %) and primiparous at the time of enrollment (71.1 % *vs.* 96.6 %). In the HIV/HBV-coinfected group CD4 level was lower and mean plasma viral load higher (1.92 log10 copies/mL *vs*. 2.31 log10 copies/ml). The proportion of cases with severe immunosuppression was similar in both groups (18. 1% *vs.* 17.9%). HBV-HIV coinfection induced a risk of prematurity of 1.51 times, but did not increase the risk of newborns with low birth weight. Conclusions: Advanced stages of HIV disease, age group 21-30 years, low CD4 counts, and low levels of education are significant risk factors for preterm birth and low birth weight. Keywords: HIV/HBV COINFECTION, PREGNANT WOMEN , PLASMA HIV RNA VIRAL LOADS.

The efficacy of antiviral therapy in the era of highly active antiretroviral therapy (HAART) has led to considerable improvement in life expectancy of patients infected with human immunodeficiency virus (HIV). Therefore, in this context, liver disease and in particular HIV/hepatitis viruses coinfection became a key issue in the management of HIV-infected patients, being a primary cause of mortality and morbidity.

Worldwide, approximately 350-400 million people are chronically HBV-infected and 40 million are HIV-infected (1). Since HIV and HBV share the same transmission routes, coinfection is likely and it is estimated that about 10% of HIV-infected individuals have chronic HBV infection (2). In HIV-infected adults, the prevalence of HBV infection rate is up to ten times higher than in the general population.

The association of HIV infection with

HBV infection and pregnancy brings to the fore a number of important issues: the effects of HBV/HIV coinfection on pregnancy, the effects of pregnancy on coinfection, management of antiviral therapy for both HBV and HIV and its effect on pregnancy as well as the prevention of vertical transmission of both viruses (3).

The prevalence of HIV/HBV coinfection in pregnant women ranges from 4% in Europe to 4-10% in Africa, 40% higher than that among the general population (2,4-7).

Several studies have addressed the issue of HBV coinfection in HIV-infected pregnant women (8-10), but the data on the prevalence of HIV/HBV coinfection among this population in Europe is scarce. Understanding the epidemiology and management of HBV and HIV coinfection in pregnant women is important because of the risk of vertical transmission.

The aim of this study was to estimate the prevalence and determine risk factors for HIV/HBV coinfection among HIV-infected pregnant patients, quantification of HBV vertical transmission in infants born to HIV/HBV-coinfected mothers, and to determine the predictors of HIV/HBV infection influence on the risk of preterm birth and low birth weight.

MATERIAL AND METHODS

The Iasi Regional HIV/SIDA Center provides assisted care to 1358 patients, of which 50% are women and 107 of them (39.19%) presenting HBV coinfection.

The study was prospective and included 74 HIV-infected subjects monitored during pregnancy in the Iasi Regional HIV/SIDA Center.

Depending on the presence of HBV coinfection the study group was divided into 2 groups that were compared in terms of epidemiological, clinical, viroimmunologic, and therapeutic features:

- **Group I** - 29 pregnant women diagnosed with HIV/HBV coinfection.

- **Group II** (control) - 45 pregnant women diagnosed with HIV infection without concomitant HBV infection.

The majority of pregnant women enrolled in the study were from the cohort receiving assisted care in the Iasi Regional HIV/AIDS Center (69 patients) to which 3 women who tested positive for HIV during pregnancy and 2 at delivery were added.

The number of prenatal visits varied depending on the time of study entry and mainly included 5 important visits scheduled as follows: at the time of pregnancy diagnosis, 10 ± 2, $24 \pm 2/34 \pm 2$ gestation weeks and immediately after birth.

Data on sociodemographic characteristics, obstetrical history and HIV history were obtained from patient monitoring records. All HIV-positive patients of reproductive age were tested for HBsAg, anti-HCV antibodies, toxoplasma antibodies, cytomegalovirus (CMV) and syphilis serology. Infants were delivered vaginally, by elective cesarean section (recommended at 38 weeks of gestation) or emergency cesarean section. Miscarriage was defined as loss of pregnancy before 24 weeks of gestation and stillbirth as fetal death after 24 weeks of gestation. Low birth weight was defined as birth weight <2500 g and preterm birth as birth before 37 weeks of gestation and after 28 weeks of gestation of an infant weighing less than 1000 grams.

The analyzed laboratory parameters were: viroimmunologic (changes in CD4 count and HIV plasma viral load over pregnancy) and metabolic (transaminase, total cholesterol, and triglyceride levels). CD4 counts were classified as <200, 200-499, and ≥ 500 cells/ml, the last determination of CD count being used in the analysis.

Evolution of HIV viral load was followed during the first, second and third trimesters of pregnancy, and the classification of undetectable HIV viral load (viral suppression) was based on analysis of the lower limit of quantification of the assay.

HBV coinfection was defined based on HBsAg positivity and included chronic infection cases and inactive HBV carrier state.

HAART was defined as a regimen of at least three antiretroviral (ART) drugs, including a combination of two nucleoside reverse transcriptase inhibitor with either a protease inhibitor or a non-nucleoside reverse transcriptase inhibitor.

The results were evaluated and interpreted by the use of frequency and structural indicators, processed using SPSS statistical functions using Student t-test, chi-square test, Pearson correlation coefficient, and linear trend. P values were considered significant at <0.05.

RESULTS

The patients enrolled in the study were aged 16 to 38 years. Most subjects, both in the coinfected and control group, belonged to age group 20-29 years age (90% *vs.* 75.5%). The mean age of coinfected patients (24.34 years) was lower than that of monoinfected subjects (25.67 years).

In both groups the majority of pregnant women (67.67% in group I *vs.* 86.65% in group II) were infected during 1989-1990 (of reproductive age at the time of study) in which the transmission route of HIV infection was believed to be nosocomial. Sexual transmission route was incriminated in a smaller proportion of subjects in the HIV/HBV group (34.5%) compared with over 50% in the controls (p=0,244) (table I).

It is worth mentioning that more than half of pregnant women in our study were married (65% in group I versus 60% in group II) (p = 0.816), and there was an unexpectedly high number of discordant couples (79.3% in group I *vs.* 73.3% in group II) (p = 0.758). According to educational level most women in group I and II had a low level (75.9% and 62.2%. respectively; p = 0.473).

TABLE I

Socioepidemiologic and viroimmunologic features by study groups

	HIV/HBV Group (no=29)	Control group (no=45)	p
Marital status			
married	19	27	0.816
discordant couples	23	33	
HIV transmission route			
parenteral	19	22	0.244
sexual	10	23	
Pregnancy			
planned	21	15	0.792
unplanned	8	30	
Mean CD4 count	389.03	253.75	0.001
Mean HIV plasma viral load			
first trimester	50 390	64 421	0.001
second trimester	51 903	20 334	0.001
third trimester	66 683	464 668	0.001

There was no difference between study groups (p = 0.516) in terms of the type of birth; in over 90% of the cases a cesarean section was performed.

Most pregnant women enrolled in the study (85%) were diagnosed before pregnancy, already receiving assisted care in the Iasi Regional HIV/AIDS Center; a small but not negligible number of patients were diagnosed during pregnancy or at the time of delivery. The time from HIV diagnosis to initiation of this study ranged from 1 to 17 years, with a mean slightly higher in the HIV/HBV group (9.93 ± 5.09 years) than in the control group (8. 13 ± 6.50 years) (p = 0.065).

As most patients belonged to age group 20-29, the so-called "long term survivors", most cases were in advanced stages, with a predominance of stage C3 in both groups: 26.1% in group I *vs*.35.6% in group II (p=0,560) (fig.1).

In both study groups predominant were the cases with CD4 cell counts 200 to 99 at/mL (53.6% *vs.* 45.5%) and severe immunosuppression was present in similar percentages (17.8% *vs.* 18.1%). The average CD4 count was significantly lower among controls (253.75 *vs.* 389.03/ml).

Individual HIV plasma viral load ranged from undetectable to a maximum of 2.310.000 copies/ml, with statistically significant differences in mean value between the 2 groups during all trimesters of pregnancy. HIV RNA level in the third trimester of pregnancy was undetectable in similar percentages in the 2 groups (36.6% *vs.* 30. 61%).

At baseline, 29.72% of the cohort had pathological ALAT levels, the proportion being higher in the HIV/HBV group than in monoinfected patients (53.6% *vs.* 15.6%. respectively); statistically significant differences were also found in average transaminases levels.

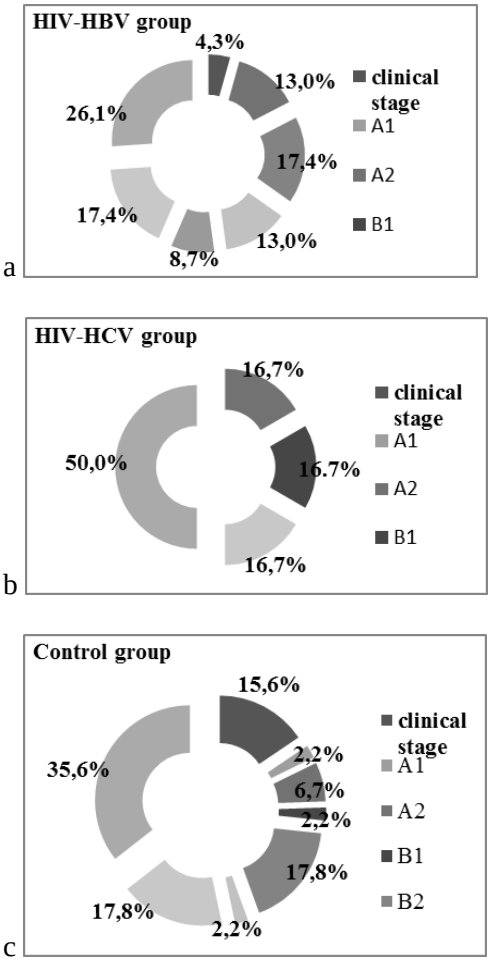

Fig. 1. Structure of study groups by disease stage

In most cases antiretroviral regimen during pregnancy consisted in a combination of two nucleoside reverse transcriptase inhibitors (NRTIs) and a protease inhibitor (86.25%), in a small number of cases (5%), "polyexperimented patients", a combination of integrase inhibitors and fusion inhibitors being used as "rescue therapy".

A far from negligible percentage of pregnant women (8.75%) did not receive prophylactic treatment, the diagnosis of HIV infection being made during pregnancy or even at birth.

To determine the influence of HIV/HBV coinfection on pregnancy outcome the risk of preterm birth and low birth weight was assessed.

Gestational age ranged from 34 to 39 weeks, the risk of premature birth in the coinfected group being 1.51 times higher compared with controls; birth weight ranged from 1750-3500 g without significant differences in mean weight between the two study groups. According to the obtained data, the significant risk factors for preterm birth and low birth weight were: advanced AIDS stages, age 21-30 years, CD4 count 200-499 cells/ml, and low level of education. In both groups no association with maternal high viral load was found (table II). Data on other risk factors for preterm delivery, such as previous obstetric history and previous and preterm deliveries were not available .

TABLE II.

Risk factors for treterm birth and low birth weigh

Risk factors	Low birth weight (no=14)	Preterm birth (no=12)	P values for chi2 test	P values for Kruskal-Wallis test
CD4 (cel/ml)				
>500	4 (28.6%)	4 (33.3%)	0.870	0.953
200-499	9 (64.3%)	7 (58.3%)	0.926	
<199	1 (7.1%)	1 (8.3%)	0.532	
VL copies/ml				
undetectable	13 (92.9%)	8 (66.7%)	0.234	
0-10.000 copii/ml	-	2 (16.7%)	0.394	0.108
10.000-100.000 copii/ml	1 (7.1%)	-	0.937	
>100.000 copii/ml	-	2 (16.7%)	0.394	
HIV clinical stage				
A	3 (21.4%)	1 (8.3%)	0.706	
B	2 (14.3%)	2 (16.7%)	0.705	0.600
C	8 (57.1%)	9 (75.0%)	0.589	
Age (years)				
<20	-	-	-	
20-30	13 (92.9%)	12 (100%)	0.937	0.937
>30	1 (7.1%)	-	-	
Level of education				
Low	10 (71.4%)	9 (75.0%)	0.811	0.811
Average	4 (28.6%)	3 (25.0%)	0.811	

The proportion of infants with detectable HIV viral load (repeated at 0,3,6, and 18 months of age) was low in the study groups (3.4% in coinfected group *vs.* 8.9% in control group) due to the fact that specific anti-HIV prophylaxis was successful in both mother and fetus in over 83% of cases. In the group with HIV/HBV coinfection the rate of HBV vertical transmission was 3.44%, as a result by cesarean delivery, breastfeeding avoidance, and successful specific anti-HBV newborn prophylaxis (table III).

TABLE III

Obstetrical and viroimunologic features in the newborns

	HIV/HBV group (n=29)	Control group (n=45)	p	RR

Undetectable	28	41	0.663	-
Detectable	1	4		
Birth weight				
≤ 2500 g	14	20	0.933	-
> 2500 g	15	25		
Preterm birth risk	12 17	13 32	0.306	1.51

DISCUSSIONS

The prevalence of HBV infection in the pregnant women followed up during the study in the Iasi Regional HIV/AIDS Center (36.25%) was much higher than that reported by other studies (11), accounted for by the epidemiological characteristics of HIV and HBV infections in Romania, the common transmission routes often allowing concomitant infection with the two viruses.

Most pregnant women included in our study belonged to the 20-29 age group, in line with the specific feature of HIV epidemic in our country, but in contradiction with the data reported by other studies; therefore, at baseline most of the cases were in advanced stages of disease.

The estimated time from the diagnosis of HIV infection to onset of pregnancy was longer than that reported by other studies (8). A possible explanation could be the particular epidemiological situation in our country, namely the group of "therapeutically polyexperimented patients".

Mean HIV plasma viral load was significantly higher in HIV/HBV coinfected patients. HIV RNA levels in the third trimester of pregnancy were undetectable at a similar rate in the 2 groups. The higher average CD4 cell count as well as the high percentage of undetectable HIV plasma viral load in the patients in our cohort differ from those reported in other articles (12). This can be explained by the fact that the majority of women of reproducible age decided to become pregnant following the indications of the infectious diseases physician of choosing the favorable period in which the viroimmunologic status allowed it.

The gestational age ranged from 34 to 39 weeks without significant differences in the mean values between the groups analyzed (p = 0.991).Compared to controls, the risk of prematurity in HIV-HBV group was 1.51 times higher. In our study a CD4 count of 200-499 cells/ml and age 21-30 years were the most important predictors of low birth

weight and preterm birth, in agreement with other published data. Advanced stages of maternal HIV infection seem to indirectly affect infant survival rate by the risk of low birth weight and preterm birth (3).

The degree of immunosuppression, high viral load, and the rate of maternal HIV disease progression increases the risk of vertical HIV-1 transmission (7, 13). In this analysis the HIV-1 related clinical manifestations were not predictive for the transmission of HBV or HIV-1. Important factors that have positively influenced the low rate of maternal-fetal transmission of these viruses were the administration of antiretroviral drugs with dual anti-VHB and anti-HIV activity, antiretroviral prophylaxis properly administered both to mother and newborn, and avoidance of breastfeeding.

The preventive role of scheduled cesarean section supports the hypothesis according to which the majority of infants are infected with these viruses during delivery (14); in our study HIV transmission to the newborn was noted in all women who delivered naturally (5 cases), without being encountered in cases with cesarean birth (9, 15-18).

Although the group of patients with ongoing pregnancy was representative, several limitations of this study should be mentioned. One limitation was that all we did was HBsAg testing of both mother and infant without having information on HBV infectivity markers and HBV plasma levels determined by PCR (12, 13). The study also had a limited ability to detect all risk factors for preterm birth as the presence of possible genetic abnormalities or obstetric factors could not be identified.

CONCLUSION

The two chronic infections can be transmitted vertically from mother to child. The large number of HIV/HBV-coinfected women of reproducible age and the presence of common risk factors detected in our study suggest that the association of HIV/HBV infections is an important public health issue.

This study provides data on the features of HIV/HBV coinfection in pregnant women, data that reflect the specific features of HIV and HBV infections in Northeastern Romania. The use of the prophylactic measures recommended by the panels of experts in the field made possible the limitation of vertical transmission of both viral infections compared with data reported in other geographical areas.

ADIPONECTIN IN PATIENTS WITH NON-ALCOHOLIC STEATOHEPATITIS (Abstract)

Aim The purpose of this study was to evaluate plasmatic levels of adiponectin in patients with non-alcoholic steatohepatitis (NASH). **Material and Methods** A cross-sectional study was conducted to evaluate a number of 104 people, 60 with NASH, and 44 healthy individuals. We used the anthropometric measurements (weight, height, BMI (body mass index), waist circumference (WC), body fat percentage (BF%)) for the assessment of the nutritional status. The biochemical analyses included fasting serum lipids, glucose profile (fasting plasma glucose, fasting plasma insulin (FPI), HOMA-IR), liver function tests, adiponectin. Insulin resistance (IR) was determined using Homeostasis model assessment (HOMA-IR). Hepatic steatosis (HS) was determined using ultrasonographic criteria and an algorithm (Hepatic steatosis index - HSI). **Results** There were statistically significant differences between groups for age, BMI, weight, HSI, FPI, HOMA-IR, adiponectin, triglycerides, and HDL-C (all $p<0.001$). In all patients, adiponectin levels were lower in men, in patients with insulin resistance (HOMA-IR>2), with obesity, and with metabolic syndrome (all $p<0.05$). In multivariate regression analysis HOMA-IR was the strongest independent factor for serum adiponectin. **Conclusions** Adiponectin levels were lower in NASH group. In multivariate regression analysis HOMA-IR was the strongest independent factor for serum adiponectin.

Keywords: ADIPONECTIN, NON-ALCOHOLIC FATTY LIVER DISEASE, HEPATIC STEATOSIS INDEX.

The prevalence of non-alcoholic fatty liver disease (NAFLD) has increased dramatically in recent years. NAFLD is the most common cause of liver disease worldwide, with a prevalence of 20%-40% in Western populations (1). Prevalence of NAFLD varies between 20-30% in European countries (2) reaching the level of 58% to 98% in overweight and obese people (3).

Adiponectin is a protein expressed by adipose tissue and hepatocytes (4). Studies have shown that decreased levels of adiponectin are associated with metabolic disorders such obesity, insulin resistance, type 2 diabetes, metabolic syndrome (5). Adiponectin is also negatively correlated

with traditional cardiovascular risk factors, such as high blood pressure, increased levels of low-density lipoprotein cholesterol and triglycerides (6,7), and is positively related to high-density lipoprotein cholesterol levels (8).

The purpose of this study was to evaluate the plasmatic levels of adiponectin in patients with non-alcoholic steatohepatitis (NASH).

MATERIAL AND METHODS

A cross-sectional study was conducted to evaluate a number of 104 people, 60 with NASH (NASH group) and 44 healthy individuals (control group CG).

Participants were recruited from three hospitals in Bucharest, Romania. The study protocol was approved by the Ethics Committee of Cantacuzio Hospital. All the participants have signed an informed written consent.

The inclusion criteria were: age over 35. The exclusion criteria were: patients with other etiology of chronic liver disease, hepatitis B, hepatitis C, autoimmune liver disease, hemochromatosis, steatosis-inducing drug use, patients having an alcohol consumption of more than 20 g/day, history of pancreatitis.

The anthropometric measurements used for the assessment of the nutritional status were: weight, height, BMI (body mass index), waist circumference (WC). Obesity was defined according to World Health Organization (WHO) classification (9). Blood pressure was measured twice with subjects in a sitting position.

Venous blood samples were drawn in the morning before 10:00 AM after a 10-h overnight fast. The biochemical analyses included fasting serum lipids (total cholesterol (TC), triglycerides (TG), high-density lipoprotein-cholesterol (HDL-C)), glucose profile (fasting plasma glucose (FPG), fasting plasma insulin (FPI), glycated hemoglobin (HbA1c)), liver function tests (aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma-glutamyl transpeptidase (GGT)). Insulin resistance (IR) was determined using Homeostasis model assessment (HOMA-IR) (10). A HOMA-IR index value of more than 2.0 was considered as criteria of IR (10). Plasma adiponectin concentration (ng/ml) was assessed by ELISA. The stages of glucose tolerance were identified according to American Diabetes Association criteria (11). MetS was defined according to the joint harmonized criteria of International Diabetes Federation (IDF) (12).

Hepatic steatosis (HS) was determined using ultrasonographic criteria and using a mathematic models - hepatic steatosis index (HSI) (13). Percentage body fat (BF%) was predicted using an equation developed in Dutch Caucasians (14).

Values were expressed as means ± SD for normally distributed data or median for skewed data. Comparisons among groups were made by use of ANOVA for quantitative variables and the $\chi 2$ test for categorical variables. Relationships between adiponectin levels and other parameters (age, BMI, %BF, waist circumference, FPG, FPI, HOMA-IR, HIS) were analysed by simple correlation and by multiple linear regressions. The values of $p<0.05$ were considered statistically significant.

RESULTS

General characteristics of the study group according to the presence of NASH were summarized in table I. There were statistically significant differences between groups for age, BMI, weight, waist circumference, HSI, AST, ALT, GGT, FPI, HOMA-IR, adiponectin, triglycerides, and

HDL-C (all p<0.001).

Among the 104 patients (26 females in CG and 33 females in NASH group), 42 patients were diagnosed with MetS (n=4, 9.1% in control group and n=38, 63.3% in NASH group) according to the modified IDF criteria. In NASH group, after stratification by gender, 21 men (77.8%) and 17 women (51.5%) had MetS (all p<0.001).

In all patients, adiponectin levels were lower in men (4.2 vs. 5.8 ng/ml, p=0.001), in patients with insulin resistance (HOMA-IR>2) (3.6 vs. 6.4 ng/ml, p<0.001), with obesity (3.42 vs. 6.4 ng/ml, p<0.001), and with metabolic syndrome (3.5 vs. 6.4 ng/ml, p<0.001). Adiponectin levels decreased with increasing BMI (fig. 1). According with the stages of glucose tolerance, adiponectin levels decreased with glucose metabolism impairment, with lowest values in persons with type 2 diabetes (2.4 ng/ml), increasing to a value of 3.2 ng/ml in persons with impaired glucose tolerance (IGT), a value of 3.79 ng/ml in those with impaired fasting glucose, and with the highest value in individuals with normal glucose tolerance (5.4 ng/ml). HSI was 31.7±4.47 in control group and 36.9±6.21 in NASH group (p<0.001). In NASH group HSI increased with age (36.6 in 35-39 years, 36.8 in 40-49 years, 39.3 in 50-59 years, 40.1 in 60-69 years)(p=0.045). The same aspect was observed in the control group (p=0.038).

In univariate analysis adiponectin was negatively correlated with age, weight, BMI, BF(%), WC, HOMA-IR, FPG, FPI, HbA1c, triglycerides, cholesterol, HSI, AST/ALT ratio, GGT (data not shown). It was observed a significant positive correlation between adiponectin and physical activity and HDL-C (data not shown). Multivariate regression analysis revealed that HOMA-IR was the strongest independent factor for serum adiponectin (table II).

DISCUSSION

In this study adiponectin levels were lower in men, in patients with insulin resistance (HOMA-IR>2), with obesity, and with metabolic syndrome. Adiponectin levels decreased with increasing BMI. Goropashnaya AV et al. found that adiponectin was inversely correlated with adiposity, assessed by either BMI or %BF (15). In other trials central obesity and intra-abdominal fat accumulation was stronger associated with decreased adiponectin levels than subcutaneous fat (16,17). Yamamoto Y. et al.(18) observed the same variation in adiponectin according to sex distribution .

In a study performed in Romania the prevalence of hepatic steatosis was 92.4% in patients with MetS (19). In our study 63.3% from patients with NASH had MetS according to the modified IDF criteria.

Increasing age is accompanied by increased visceral adipose tissue, insulin resistance and decreased adiponectin. In our study HSI raised with increasing age in both groups.

Adiponectin was positive correlated with physical activity and HDL-C. Lifestyle intervention would favorably affect adiponectin levels, also presenting beneficial effects upon the pathogenic processes such as inflammation, hepatic steatosis, fibrogenesis.

In our study multivariate regression analysis revealed that HOMA-IR was the strongest independent factor for serum adiponectin.

There are several limitations of this study: small sample size, assessement of insulin resistance using a mathematical model (HOMA-IR), and hepatic steatosis using a mathematical model respectively ultrasonographic criteria.

CONCLUSIONS

In this study adiponectin levels were lower in men, in patients with insulin resistance (HOMA-IR>2), with obesity, and with metabolic syndrome. Adiponectin levels were lower in NASH group. Adiponectin was negatively correlated with traditional cardiovascular risk factors. Thouth in multivariate regression analysis HOMA-IR was the strongest independent factor for serum adiponectin. Prospective studies should demonstrate that lowering insulin resistance through non-pharmacological and/or pharmacological measures would increase adiponectin levels and reduce cardiovascular risk.

NONALCOHOLIC FATTY LIVER DISEASE AND ITS COMPLICATIONS - ASSESSING THE POPULATION AT RISK. A SMALL SERIES REPORT AND LITERATURE REVIEW (Abstract): **The aim** of the study was to highlight correlations between serum biochemical markers and different degrees of liver inflammation or fibrosis revealed by liver biopsy in morbidly obese patients. We also wanted to emphasize that the occurrence of hepatocellular carcinoma (HCC) is increasingly associated with obesity, metabolic syndrome and nonalcoholic fatty liver disease. **Material and methods:** A clinical retrospective study was carried out on a series of 13 patients operated for morbid obesity in our surgical unit. Included in this study were only the obese patients referred for bariatric surgery without other risk factors for liver disease and in whom a liver biopsy was taken during metabolic surgery. **Results:** The pathology report revealed different stages of nonalcoholic fatty liver disease in all 13 patients: pathological features of steatohepatitis (7 patients), hepatic steatosis (5 patients) and lesions specific for evolving cirrhosis (1 patient). Regardless of the pathological changes of the liver, except the patient with evolving cirrhosis, none of these patients showed changes in classical liver function blood tests. **Discussions:** Hepatic alteration in obese patients, ranging from simple steatosis to steatohepatitis or even cirrhosis, is not always correlated with the values of classical biological liver function tests. Literature data suggest the involvement of adipokines in the development and progression of steatosis as the hepatic expression of metabolic and chronic inflammation syndrome occurring in obese patients. Furthermore, these proteins secreted by adipose tissue seem to be related to the HCC occurrence. However, none of these studies show the exact pathway followed by the hepatic cell from simple fatty liver to hepatocellular carcinoma. C**onclusions:** finding and selecting the population at risk for fatty liver disease progression and for HCC development among obese patients is mandatory. **Keywords:** OBESITY, NAFLD, HCC, BARIATRIC SURGERY.

Obesity is defined by the World Health Organization (WHO) as an abnormal or excessive fat accumulation that may impair health, with body mass index (BMI) greater than or equal to 30 kg/m^2 (1). WHO and International Obesity Task Force reported that 312 million adults worldwide are obese. Overall, more than one in 10 of the

world adult population is obese (2). According to International Agency for Research on Cancer (IARC), hepatocellular carcinoma (HCC) is the fifth most common cancer in men and the seventh most common cancer in women, with more than 500,000 new cases per year (3, 4). It is already established that chronic conditions such as viral hepatitis B and C, alcoholic liver disease and hemochromatosis are the main risk factors for developing HCC. Nowadays, due to the growing number of cryptogenic HCC (with no readily identifiable risk factor) along with a dramatic increase in the number of patients with nonalcoholic fatty liver disease (NAFLD) related to obesity and metabolic syndrome, the association of these pathological conditions is becoming a topic increasingly discussed.

NAFLD comprises a spectrum of liver diseases defined by excessive fat accumulation in the form of triglycerides (steatosis) in the liver which cannot be explained by alcohol consumption. It ranges from simple steatosis to non-alcoholic steatohepatitis (NASH) that can have different degrees of fibrosis and can progress to liver cirrhosis and end-stage liver disease. Among patients with NAFLD, one to two in each ten patients will have NASH (5). A recent survey showed that NAFLD-associated cirrhosis is the third indication for liver transplantation in the United States, and it is expected to be the number one indication in 2020 (6).

NAFLD is strongly associated with obesity, insulin resistance (IR) / type 2 diabetes mellitus (T2DM) and the metabolic syndrome. In overweight subjects, the prevalence of steatosis is at least two times more frequent than in lean subjects (7), being directly proportional to the increase of body mass index.

Although cirrhosis precedes the diagnosis of HCC in most individuals, the number of cases in which HCC develops in the absence of cirrhosis is not negligible. A clinical-histopathological review of 804 American patients with HCC confirmed the lack of cirrhosis in as many as 42.6% of all cases (8). A recent review of a United States healthcare claims database covering 18 million lives per year identified 4406 cases of HCC associated with NAFLD as the most common underlying risk factor (59%) followed by diabetes (36%) and chronic HCV infection (22%) (9). Only 46% of all NAFLD-associated HCC cases were reported to have cirrhosis in this study, while 78% of HCC cases associated with chronic hepatitis C occurred in cirrhotic liver (9).

MATERIAL AND METHODS

With the increasing number of bariatric surgeries in our service, we started to take liver biopsy during bariatric surgical intervention as a diagnostic method of liver damage. We retrospectively reviewed the medical records of 13 obese patients receiving sleeve gastrectomy and hepatic biopsy during the past three months in our surgical unit. Inclusion criteria: patients aged over 18 years meeting the NIH criteria for bariatric surgery, irrespective of age, sex or geographical origin. The NIH criteria for bariatric surgery are BMI $\geq$40 kg/m^2 or BMI $\geq$35 kg/m^2 and at least one significant weight-related co morbidity (10). Exclusion criteria: patients diagnosed with viral hepatitis B and C, history of any liver disease, chronic treatment with hepatotoxic drugs or alcohol consumption over 20g per day. Also excluded were the patients in whom liver biopsy was not taken due to

patient refusal or any technical reasons. In all study patients age, clinical parameters (BMI), medical history, pathology reports and biological parameters (AST, ALT, GGT, ALP, PLT, HOMA-IR, Ferritin) were reviewed.

RESULTS

The patients had a median age of 36.25 years and a BMI ranging from 44.19Kg/m^2 to 60 Kg/m^2, with a median BMI of 48.04 Kg/m^2.

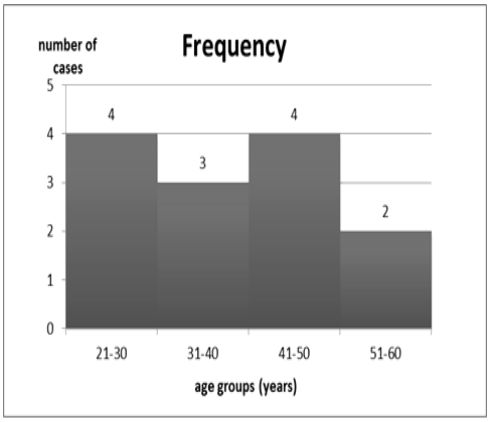

Fig. 1. Age histogram

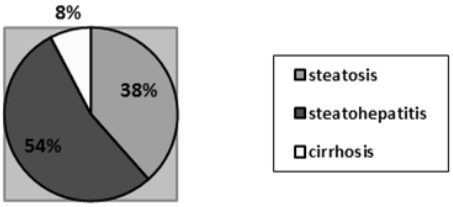

Fig. 2. Hepatic features in obese patients

The pathology reports of all these 13 patients who underwent sleeve gastrectomy and hepatic biopsy showed different stages of nonalcoholic fatty liver disease. The histological changes in the liver ranged from simple steatosis (5 patients) to steatohepatitis (7 patients) expressed by ballooning degeneration of hepatocytes and vacuolation of the nuclei with additional portobiliary fibrosis- in 2 cases; one patient presented obvious features of evolving liver cirrhosis.

Noteworthy, except for the patient diagnosed with liver cirrhosis who presented a slight increase in AST value (AST=49U/L), none of the patients diagnosed with any stage of fatty liver disease had pathologic changes of ALT, AST, GGT or ALP. They also had normal thrombocyte levels and normal coagulation. As to biological markers, we noticed elevated ferritin in 2 of the patients with hepatic steatosis, 3 of the patients with steatohepatitis and 1 patient with evolving cirrhosis; moderately increased cholesterol levels were found in 6 cases of steatohepatitis (range 203mg/dl-271mg/dl). Concerning obesity-related comorbidities, only 2 patients had history of type II diabetes and 1 patient was on antihypertensive therapy. According to HOMA-IR test, moderate insulin resistance was detected in 4 nondiabetic patients (2 of them having steatohepatitis and 2 hepatic steatosis); we considered that in the two study patients with type 2 diabetes abnormal HOMA-IR was a common situation.

DISCUSSION

Although the number of cases included in the study is small, our study shows that, except for the patient with evolving cirrhosis who presented a slight increased AST level, liver disease demonstrated by pathological examination had no impact on liver transaminases, blood count, alkaline phosphatase or coagulation tests. The results are in accordance with recent literature data showing that patients with normal versus elevated ALT had similar severity of

NASH and suggesting that plasma aminotransferase levels are misleading parameters for guiding clinical management (11).

Calculation of APRI (aspartate aminotransferase to platelet ratio index) showed values ranging from 0.135 to 0.297 with a median of 0.232; values higher than 0.5 were found in patient diagnosed with liver cirrhosis (0.572) and in one of the two patients presenting steatohepatitis and liver fibrosis (0.508). These data are partly in concordance with literature data showing that APRI values ≤ 0.3 and ≤ 0.5 rules out significant fibrosis and cirrhosis (12).

In recent years, adipose tissue has been considered an endocrine organ because of its capacity to secrete a variety of proteins named adipokines, with broad biological activities. The adipose tissue expansion may occur in inert subcutaneous tissue but the metabolically active adipose tissue is the visceral fat. The incrimination of the activity of adipokines in the development of associated morbidities makes them among the most studied proteins today. Even so, the exact causal link between obesity, secretion of adipokines and the hepatic manifestation of metabolic syndrome - nonalcoholic liver disease with its possible complications, steatohepatitis, liver cirrhosis and even hepatocellular carcinoma has not been found.

Speaking of the least common but most dangerous morbidity associated to NAFLD, the incriminated mechanisms in hepatic carcinogenesis related to NAFLD are insulin resistance, oxidative stress and lipotoxicity, on a background of low-grade inflammatory status associated with obesity and metabolic syndrome. Another important factor that contributes to the pathogenesis of HCC is hyperinsulinemia, resulting in increased insulin growth factor-1 (IGF-1) which has important proliferative and antiapoptotic effects. IGF-1 promotes angiogenesis through increased vascular endothelial growth factor production, which in turn leads to cancer cell proliferation (13). In our study group, excepting the two diabetic patients, we detected 4 more cases with elevated insulin, 2 patients presenting steatohepatitis and 2 steatosis.

Normally, insulin suppresses lipolysis, hydrolysis of triglycerides to free fatty acids (FFA). In conditions involving insulin resistance, such as fatty liver disease, lipolysis is active, resulting in the release of FFA from the adipose tissue. Insulin resistance (IR) has a major role in the occurrence of hepatic steatosis and in the progressive development of steatohepatitis, liver cirrhosis and even hepatocellular carcinoma. Steatosis itself also promotes IR, endorsing a self-perpetuating vicious cycle (14). The excessive accumulation of fat in adipocytes promotes an increase in oxidative stress, which deregulates adipocytokines production and promotes low grade inflammatory state in the adipose tissue, through the release of interleukin (IL)-6 among others (15). Subsequently, macrophages and lymphocytes are activated, promoting further release of pro inflammatory cytokines, such as tumor necrosis factor (TNF)-α and interferon-γ. The spillover of FFA from the adipose tissue leads to ectopic accumulation of fat in muscles and liver. Noteworthy, in the liver, not all insulin actions are impaired; it preserves its lipogenic actions further inducing steatosis, and its pro-mitogenic actions, which may enhance hepato-carcinogenesis (16). Excepting the two patients with type 2 diabetes in whom abnormal HOMA-IR was a common situation, moderate IR was present in 4 nondiabetic patients (2 with

steatohepatitis and 2 with hepatic steatosis).

Increased serum ferritin levels are present in more than 30% of patients with NAFLD and it has been reported to correlate with IR and the other metabolic abnormalities defining the metabolic syndrome (17, 18). Our data are consistent with the literature data, showing increased ferritin levels in 46.15% of our NAFLD patients, changes not related to a specific degree of liver damage. Other mechanisms involved in hepatic disorders up to HHC development, such as hepatic iron overload, seem to be linked to IR and metabolic syndrome (19). Iron overload has been hypothesized to induce IR by catalyzing oxidative stress in the liver (20). The iron may fuel oxidative stress-driven cell toxicity or activate signaling pathways involved in fibro genesis or carcinogenesis occurring in the metabolic syndrome (18). Metabolic derangement and progression of liver disease are more severe with NASH than with NAFLD and hepatic iron deposition has been shown to increase the risk of malignant transformation in NASH-derived cirrhosis (17, 21). Considering these data, we believe that the assessment of liver iron overload should be part of the diagnosis of NASH.

All these mechanisms have in common the involvement of adipokines in their occurrence and development. Leptin, a protein mainly produced by adipose tissues is best known as a regulator of food intake and energy expenditure via hypothalamic-mediated effects. This adipokine has many additional effects, including angiogenesis - by induction of VEGF activation with an important impact on liver fibrosis, as formation of new blood vessels is a key component of the wound-healing, with important implications in the development of liver fibrosis, cirrhosis and HCC (22). Considering that obesity induces a chronic inflammatory status, it has been demonstrated that leptin also has a regulatory immune function. Leptin levels are acutely increased by, and also may affect the secretion of many acute phase factors such as tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6 (23, 24). Both dietary and genetic obesity promote liver inflammation and tumor genesis by enhancing IL-6 and TNF expression (25). As we can see, hepatic impairment in obese patients, ranging from simple steatosis to steatohepatitis or even cirrhosis, does not always have an impact on classical biological liver function test values. Liver biopsy remains the gold standard for differentiating nonalcoholic steatosis from other stages of fatty liver disease; still, it is an invasive procedure, associated with morbidity, mortality and several limitations (26). The clinical experience shows that most patients refuse invasive methods for assessing the progression of liver pathology associated with obesity. Therefore we believe that finding a noninvasive algorithm for assessing the degree of liver damage and especially the evolution of liver lesions after bariatric surgery is required.

CONCLUSIONS

As our study shows, the number of cases of nonalcoholic steatohepatitis with different degrees of liver fibrosis that do not present any pathological changes in liver function blood tests is not to be neglected. There is increasing evidence that obesity, associated metabolic disorders and mainly NAFLD - the hepatic expression of metabolic syndrome - are involved in the development of HCC. The incidence of

HCC occurrence in patients with NAFLD is low, but the number of obese patients is increasing constantly worldwide. A worrying fact is that cirrhosis is not indispensable for HCC development in patients with NAFLD. For an efficient follow-up, noninvasive algorithms to assess liver damage in patients with morbid obesity as well as selection criteria of patients at risk to develop HCC among patients with obesity and metabolic syndrome are needed.

NEWS

SURGICAL TREATMENT OF AORTIC VALVE ENDOCARDITIS: A 26-YEAR EXPERIENCE

Microbial infection of the endothelial lining of any part of the heart, infective endocarditis (IE), is an uncommon but life threatening condition. Despite advances in diagnosis, antimicrobial therapy, surgical techniques, and management of complications, the incidence has not decreased in the past 30 years and patients with IE still have high morbidity and mortality rates related to this condition. Its management aims to eradicate the infecting organism as soon as possible mainly with antibioticotherapy but clinical complications and treatment failure suggest surgery up to 60% of the cases. IE effecting aortic valve accounts about 40-67% of all cases and about 60-70% of these cases undergo surgery in the acute phase. In spite of the high mortality and morbidity it carries, surgical therapy is still the mainstay in the treatment of aortic valve IE. Numerous studies have assessed different risk factors for mortality and morbidities in the treatment of IE but risk factors for surgical treatment of aortic valve IE patients need to be clarified. In this study, authors retrospectively assessed the results of the surgical treatment of patients with aortic valve endocarditis over a period of 26 years in an attempt to address these issues (Adademir T, Tuncer EY, Tas S et al. Surgical treatment of aortic valve endocarditis: a 26-year experience. *Rev Bras Cir Cardiovasc* 2014; 29 (1): 16-24).

CHRONIC OCCUPATIONAL STRESS EXPOSURE MAY INCREASE THE VULNERABILITY TO ACOUSTIC TRAUMA IN MILITARY PROFESSIONALS (Abstract): Today little is known about the connection between chronic stress exposure and hearing loss. These effects cannot be explained by differences in HPA axis response but recent studies saying that chronic stress induced limbic system alterations spread to nonlimbic areas affecting auditory system might be the key. On the other hand we know that subjects exposed to chronic stress may prove hypersensitivity to novel stressors. **The aim** of this study is to confirm that occupational chronic stress (OCS) exposure determines vulnerability to acoustic trauma and to establish a method to identify individuals at risk prior to their exposure to high intensity acoustic stimulus. **Material and methods:** 60 military personnel with known acoustic trauma injury evidentiated through audiograms and occupational chronic stress exposure quantified through validated questionnaires were exposed to mild novel stressor: occupational medicine evaluation and clinically assessed for maladaptive cardiovascular response (MCVR). Employees were split in two groups, group 1 (MCVR) and group 2 (non MCVR). **Results:** We found positive correlation between level of perceived OCS and level of hearing loss on entire group and between groups with values of parameters significantly higher in group 1. Subjects exposed to OCS with hypersensitivity to novel stressor evidentiated through maladaptive cardiovascular stress response may be more vulnerable to high intensity acoustic stimulus and consequently acoustic trauma. **Conclusions:** Establishing methods and biomarkers that help us indentify individuals at risk of developing acoustic trauma might decrease the high burden of hearing loss. **Keywords**: CHRONIC OCCUPATIONAL STRESS, HYPERSENSITIVITY, NOVEL STRESSOR, ACOUSTIC TRAUMA

Hearing is a critical sensor for survivability and lethality in military operations, the ability to accomplish unit's mission being directly proportional to ability to communicate effectively. Besides the roles of hearing in a peace operation: identifying sound source, understanding verbal orders, radio communications, in a combat we have to take in account the chaotic environment, the complexity of problems encountered and the reaction time required, so a mild impairment of hearing in a peace operation might be judged differently in a combat situation (1). Hearing loss (HL) was considered an invisible injury viewed as acceptable by product of military service with little impact on military operations but 55864 veterans compensations cases between 2001- 2006 summing 900 ml $ made HL a primary disability second only to

tinnitus and a huge burden (2). In a combat sound is often the first source of information before direct contact. Information carried by sound comes from all directions, through darkness and over or through visual obstacles. Aggressive action produces sounds that cannot be camouflaged. The ability to hear and recognize combat relevant sounds is a vital component to situational understanding and provides tactical advantage. So noise induced hearing loss is a tactical risk and threatens both individual and unit combat effectiveness and preserving hearing capabilities of an unit is an important challenge for the medical team involved in prevention (1). Any factor that may influence good hearing capability should be thought of and considered in situations, peace and combat.

Recent studies pointed out that chronic stress determines limbic system alterations that spread to non limbic areas affecting specific sensory systems such as auditory system and complex cognitive functions (3). Moderate or high stress levels at the time of acoustic trauma might play a pivotal role in the vulnerability of the cochlea to acoustic damage (4). Chronic stress induces dendritic atrophy in auditory cortex thus influencing complex cognitive behavior with impact on auditory attention and decision making processes and decrease in environmental adaptation. We might so easily imagine a scenario in which a chronic stress exposed military with maladaptive cardiovascular stress response (MCVSR) or white coat effect pattern with subsequently exaggerated alarm reaction is put in front of the wide variety of stressors in an operational theater (5, 6, 7, 8, 10). His impaired processing sound characteristic transforms him in a possible candidate for noise induced hearing loss or worse affecting direct performance and safety of the military operation (1, 2, 11).

That is why best preventive measures must be taken before the units are involved in high-stress, high-risk actions (9).

Following this logic we thought that we can identify individuals at risk of developing hearing loss prior to their exposure to high intensity acoustic stimulus by looking at their cardiovascular stress response pattern.

MATERIAL AND METHODS

Our study is open label randomized type of study done on 60 military personnel, all males, recruited during routine occupational medical evaluations in the occupational medical office from Emergency Military Hospital, Iasi. The selection was based on inclusion and exclusion criteria. The inclusion criteria were bilateral acoustic trauma with hearing loss disability ≥30dB in 4,000 Hz with age correction factor (Romanian occupational health diagnostic standards for acoustic trauma), healthy with no relevant personal or family history, BMI<25, level of perceived work stress > 5 (significant level of perceived occupational stress) on occupational stress evaluation validated questionnaires and exclusion criteria were unilateral acoustic trauma, cardiovascular disease, endocrine disease, neurologic disease, obesity and level of perceived work stress < 5.

We considered the occupational medicine routine evaluation a mild novel stressor and cardiovascular dysfunctions discovered (arterial blood pressure ≥ 140/80 mm Hg and rest heart beat >80 bpm) an exaggerated alarm reaction and anxious behavior of a chronic occupational stressed hypersensitive subject. We divided the entire group in two, group 1 being the MCVSR

group with cardiovascular dysfunctions and group 2 being the non MCVSR group with normal cardiovascular stress response and normal values of cardiovascular parameters. Than we studied the differences between the two groups and the entire group in terms of level of stress, level of exaggerated alarm reaction (values of cardiovascular parameters) and hearing loss levels. We were looking in our research for confirmation or not that chronic occupational stress exposure determines increased vulnerability to acoustic trauma and if the answer was positive to establish a method to identify individuals at risk of developing it prior to their exposure to high intensity acoustic stimulus.

RESULTS AND DISCUSSION

We used descriptive statistic and inferential statistic parameters from *SPSS 11.0*. We found a high level of work stress: 7.1 ±0.89 on entire group with positive significant correlation of medium strength: r-0.455 between hearing loss level and level of work stress on entire group and positive significant correlation of high strength- r-0.695 between hearing loss level cardiovascular parameters modifications on entire group.

TABLE I

Comparative values between the two groups (MCVSR-group1 and non MCVSR-group2) in hearing loss and occupational stress level

Group	N	HLBE	HLWE	MHL	OccSL
MCVSR-group 1	28	45.96±9.98	59.78±9.36	52.87±8.47	7.42±0.74
nonMCVSR-group 2	32	37.03±5.04	42.37±6.52	39.70±5.20	6.81±0.93

HLBE- hearing loss best ear; HLWE- hearing loss worst ear; MHL- medium hearing loss; OccSL- occupational stress level; MCVSR- maladaptive cardiovascular stress response.

The differences found between the two groups in terms of hearing loss and occupational stress levels suggest that military exposed to chronic stress with exaggerated alarm reaction and maladaptive cardiovascular pattern might have a vulnerability to acoustic trauma with higher levels of hearing loss thus confirming the existed data in scientific literature and recent studies. Cardiovascular stress response can be used to early identify individuals at risk of developing noise induced hearing loss prior to their involvement in high-stress and high-risks operations. We need to confirm the relationship with broaden studies and in larger groups.

CONCLUSIONS

We found out that military subjects exposed to high level of work stress that have maladaptive cardiovascular stress pattern may be more vulnerable to high intensity acoustic stimulus and consequently acoustic trauma, this being in accord with recent scientific data. The pattern can be easily recognized and used as biomarker for early identification of individuals at risk of developing hearing problems prior of their deployment.

Establishing methods and biomarkers that help us identify individuals at risk of

developing acoustic trauma might decrease the high burden of hearing loss and preventive interventions as part of military health strategies might decrease the occurrence of stress related hearing problems.

IMPACT OF HEPATIC STEATOSIS ON DISEASE COURSE IN PATIENTS WITH COMPENSATED HEPATITIS C VIRUS-RELATED CIRRHOSIS RECEIVING INTERFERON-FREE THERAPY (PARITAPREVIR, RITONAVIR, OMBITASVIR DASABUVIR AND RIBAVIRINA) (Abstract). **Aim**: In Romania, genotype 1 of hepatitis C virus (HCV) is the most common and the aim of this study was to assess comparatively the biochemical, hematological and virological parameters in patients with different degrees of steatosis before the initiation of interferon-free therapy (paritaprevir/ritonavir/ombitasvir/ dasabuvir plus ribavirin) (PrOD-R) and at its completion. M**aterial and methods:** This retrospective study included 113 patients with compensated liver cirrhosis with C-genotype 1b, treated with PrOD-R evaluated and clinically-biologically monitored at the Iasi Hospital of Infectious Diseases between November 2015 and May 2017**. Results**: We found an advanced steatosis (grades ≥2) in 54% of patients. Associated cardiovascular and kidney diseases and diabetes mellitus were more frequent in the group of patients with advanced steatosis compared to the group with incipient steatosis (19.5% *vs*. 8% and 10.6% *vs*. 0.9%, respectively) (p = 0.02 and p = 0.003, respectively). In most patients the hepatic cytolysis syndrome was identified before the initiation of therapy (93%) with a significant difference between patients with advanced versus low grade steatosis (53% *vs*. 40%, respectively, p = 0.014). In patients with steatosis grade ≥2, GGT levels above the normal range were detected in 52.2% cases and in the group with steatosis grade <2 in 31% (p = 0.0003). At the time of treatment initiation, only 3.5% of patients presented various grades of anemia, but at the end of therapy 38% had different grades of anemia, this anomaly being more common in patients with advanced steatosis (23% *vs*. 15%, respectively, p = 0.27). At the end of therapy, only 14.2% still had higher-than-normal ALT levels, most of them in the group with advanced steatosis (11.5% *vs*. 2.6%, respectively, p = 0.018). **Conclusions**: We found a significant correlation between the

advanced grade of hepatic steatosis and the levels of hepatic cytolysis enzymes and GGT both before initiation of therapy and at its completion in patients with advanced steatosis.
Keywords: STEATOSIS, HCV CIRRHOSIS, INTERFERON-FREE TREATMENT.

HCV infection has been reported to be strongly associated with hepatic steatosis. But there are other factors responsible for steatosis, including alcohol consumption, obesity and diabetes.

Experimental animal studies have shown that HCV core protein promotes liver steatosis. Also, when steatosis was studied in connection with HCV genotypes, it was found that although steatosis is induced by all HCV genotypes, it appears to be more evident and more frequent with genotype 3 infection, in these patients being a good correlation between the steatosis grade and HCV replication, the presence of HCV core protein in the liver, respectively (1). Moreover, it has been reported that in patients with genotype 3 infection steatosis regresses with successful antiviral therapy compared to those with other genotypes that remain steatosis (2).

Different mechanisms have been incriminated in the alteration of the lipid metabolism and steatosis progression in HCV-infected patients:

(1) *Abnormal VLDL secretion*;

(2) *Increased de novo free fatty acid synthesis*;

(3) *Abnormal AGL degradation* (3,4,5).

Several viral proteins can occasionally cause cell lesions (by oxidative stress and steatosis), probably in a specific sequence and directly activating the hepatic stellate cells without participating in the inflammatory response (6). These findings may explain why some chronic hepatitis C patients may present significant fibrosis at the histological assessment, despite normal liver enzymes and minimal/ mild inflammation.

It is known that steatosis is a cofactor that influences the progression of fibrosis in chronic hepatitis C. Various studies have directly associated steatosis with HCV genotype 3. Thus, Kumar et al. identified steatosis reduction as a predictor of the virological response in the treatment of chronic hepatitis C in individuals infected with genotype 3 (2).

Our study aimed to evaluate the impact of advanced steatosis grade on virological, hematological and biochemical parameters in patients with HCV cirrhosis treated with Ombitasvir + Paritaprevir + Ritonavir + Dasabuvir and Ribavirin.

The need for such an assessment is justified by the existence of regional particularities regarding comorbidities, diet, age at the time of treatment, previous use of an antiviral drug and the response to it.

MATERIAL AND METHODS

In this retrospective study, we analyzed 113 patients with a diagnosis of compensated liver cirrhosis, with HCV genotype 1b, assessed, treated and clinically-biologically monitored at the Iasi “St. Parascheva" Hospital of Infectious Diseases (section 2) from November 2015 until May 2017.

Patient selection was strictly guided by the inclusion criteria set forth in the therapeutic protocol appropriate to DCI (Ombitasvirum + Paritaprevirum + Ritonavirum + Dasabuvirum, currently in force (7, 8).

Patient analysis required the collection and systematization of personal data of

epidemiological, clinical and laboratory relevance from the medical records and the creation of databases (*Excel, SPSS*) for statistical evaluation and interpretation.

Statistical analysis. The chi-squared test was used for statistical analysis and a value of $p<0.05$ was considered statistically significant.

Ethical statement. The objectives and procedures of the study were approved by the Ethics Committee of the Iasi Infectious Diseases Hospital. No written consent was given by the participants, as data were collected and analyzed anonymously.

RESULTS

In all patients, steatosis was graded using the baseline Fibromax test. We found an incipient steatosis (<2) in 52 (46%) patients and advanced steatosis (≥2) in 61 (54%) patients Extreme steatosis grades, namely S0/S0-1 and S3, were recorded in 19 (18%) patients and 34 (30%) patients, respectively.

Seventy-five (66.37%) patients had been previously treated with peginterferon and ribavirin; of them 54 (47.8%) were considered non-responders to previous treatment and 21 (18.6%) patients relapsed. Thirty-eight (33.62%) patients did not receive previous interferon-based regimen.

Efficacy and safety of therapy were assessed in patients with advanced steatosis (≥2) and compared with data from patients with incipient steatosis (< 2) (tab. I).

TABLE I

Response to previous treatment with interferon + ribavirin and the presence of comorbidities by steatosis grade

	Steatosis<2 (no=52)		Steatosis≥2 (no=61)		Total (no=113)		p
	No	%	No	%	No	%	
Previous interferon-based regimen. (no=75)							
- Non-responder	27	36	27	36	54	47.8	0.85
- Relapse	11	14.7	10	13.3	21	18.6	
Treatment naïve (no=38)	14	12.4	24	21.3	38	33.6	0.16
With cardiovascular or kidney disease (no=31)	9	8%	22	19.5	31	27.4	**0.02**
With diabetes mellitus (no=13)	1	0.89	12	10.6	13	11.5	**0.003**

A higher rate of the patients with cardiovascular, kidney and metabolic (diabetes mellitus) were in the advanced steatosis group compared with the early steatosis group (19.5% versus 8% and 10.6% *vs*. 0.9%, respectively) ($p = 0.02$ and $p = 0.003$, respectively).

Nearly half of the patients had thrombocytopenia (<150,000 / mm^3) at baseline and was identified in a slightly higher rate in the patients with steatosis ≥2 compared to those with steatosis <2 (28% *vs*. 22%, $p = 0.64$).

The hepatic cytolysis syndrome was identified before the initiation of treatment in most patients (93%) with a significant difference between those with advanced steatosis versus those with low-grade steatosis (53% *vs* 40%, respectively, $p = 0.014$).

TABLE II

Hematologic and biochemical parameters at the initiation of therapy PrOD- R by steatosis grade

Parameters at the initiation of therapy	Steatosis <2 (no=52)		Steatosis ≥2 (no=61)		Total (no=113)		p
	No	%	No	%	No	%	
Anemia (Hb<11g/dL)	1	0.9	3	2.7	4	3.5	0.39
Thrombocytopenia (<150,000/mmc)	25	22	32	28.3	57	50.4	0.64
Increased ALT level*	45	39.8	60	53.1	105	92.9	**0.014**
Increased bilirubin level (>1.2mg/dL)	11	9.7	9	8	20	17.7	0.11
Increased GGT level (>65UI/L)	35	31	59	52.2	94	83.2	**0.0003**
Increased AFP level >20 UI	11	9.7	14	11.5	25	22.1	0.81

*> 30 UI in women and > 40 UI in men

In the study patients, not only the level of cytolytic enzymes was directly influenced by the steatosis grade but also the level of cholestasis enzymes. Thus, in patients with steatosis ≥2, elevated GGT levels were detected in 59 cases (52.2%), and in the group with steatosis<2, 35 patients (31%) showed levels above the normal (> 65UI /L) (p = 0.0003) (tab. II).

Approximately 18% of patients had initially mild hyperbilirubinemia, with no significant differences between the two study groups.

More clear-cut was the comparison of the extreme steatosis grades (S0 *vs.* S3) with respect to mean levels of viral load, ALT, GGT and AFP at baseline. Statistical analysis revealed significant differences between the obviously higher values in those with significantly advanced steatosis compared to those without steatosis.

Comparing the mean ALT levels in patients with steatosis S0 (71 IU) and steatosis S3 (172 IU), we noticed the significant influence of steatosis grade on the level of this enzyme (p = 0.002) (tab. III).

TABLE III

Mean levels of viral load, ALT, GGT and AFP at baseline by steatosis grade

Mean levels	Steatosis: S0 (n=19)	Steatosis: S3 (n=34)	p
Mean viral load (UI/mL)	582,450	1,613,050	**0.048**
Mean ALT	71 UI	172 UI	**0.002**
Mean GGT	42.3 UI	162.4 UI	**0.0003**
Mean AFP	5.37 UI/mL	30.82 UI/mL	**0.018**

Alpha-fetoprotein (AFP) is a very important parameter in the initial assessment being a predictor of hepatocellular carcinoma. In our study, we found a clear relationship between steatosis grade and AFP level. Thus, in S0 patients, mean AFP was 5.37 IU/mL compared to 30.82 IU/mL in S3 patients (p = 0.018).

If only 4 (3.5%) patients had anemia at baseline (Hb <11g/dL), at the end of therapy, 38% had different degrees of anemia, this hematological abnormality being more common in advanced steatosis cases (23% *vs.* 15%, respectively, p = 0.27) (tab. IV).

We also noticed a significant reduction in the number of thrombocytopenic patients

at completion of antiviral therapy from 50% at baseline to 34%, in contrast to the elevation trend of bilirubin (from 17% at baseline to 31% at the end therapy).

TABLE IV

Hematological and biochemical parameters at the end of PrOD- R therapy by steatosis grade

Parameters at the end of therapy	Steatosis <2 (no=52)		Steatosis ≥2 (no=61)		Total(no=113)		p
	No	%	No	%	No	%	
Anemia (<12 g%)	17	15	26	23	43	38	0.27
Thrombocytopenia (<150,000/mm^3)	19	16.8	19	16.8	38	33.6	0.54
Increased ALT level	3	2.7	13	11.5	16	14.2	**0.018**
Increased bilirubin level (>1.2mg/dl)	20	17.7	15	13.3	35	31	0.11
Increased GGT level (>65UI/l)	4	3.5	15	13.3	19	16.8	**0.016**
Increased INR ↑ level (>1.2)	44	38.9	53	46.9	97	85.8	0.73

Most of the treated patients responded by the return to normal of liver cytolytic enzymes, only 14.2% continuing to show ALT above the normal level at the end of therapy, their proportion being significantly higher in those with advanced steatosis (11.5% *vs.* 2.6%, respectively, p = 0.018).

A favorable evolution was also recorded for GGT; thus, only 16.8% of the treated patients had higher-than-normal levels, with significant differences between those with steatosis ≥2 *vs.* those with S <2 (13.3% *vs.* 3.5 %, respectively, p = 0.016).

A sustained virological response was recorded in all cases (at 12 weeks after completion of therapy) except for one person who discontinued medication for 4 days because of a death in the family.

DISCUSSION

The severity of hepatic steatosis in chronic HCV infection is due to the combination of several host factors (obesity, medication, alcoholism) and viral factors (genotype, viral load, mutations) that interfere with the hepatocyte lipid metabolism. Thus, steatosis occurs in chronic HCV infection more frequently than in any other chronic hepatitis and, more importantly, in patients with no other causes of fatty liver, indicating that hepatic steatosis is a direct cytopathic effect of the virus. That is why we considered extremely important to evaluate several aspects related to the presence and severity of steatosis in the study patients (2).

Of the total of 113 patients, 91.2% (103 patients) had various grades of steatosis, with a moderate-severe steatosis (grade ≥2) in over half of them. These results reveal a higher prevalence of steatosis in the study group compared to literature data reporting a prevalence of steatosis in patients with chronic HCV infection of 40-86% (9) or, in another case, of only 55% (10).

Another important aspect is the relationship between the viral genotype and the prevalence of steatosis. As already men-

tioned, all patients included in the study had HCV genotype 1b infection. It was determined (by Fibromax) that 90% of patients had various grades of steatosis, value significantly higher than those reported by other studies which showed a prevalence of steatosis in patients with HCV genotype 1 infection of about 50% (10). Also, most studies suggest that genotype 3 is the most steatogenic, with a prevalence of steatosis of >70%, associating it with the lowest rate of response to classical interferon-based therapies (10).

The introduction of new antiviral agents with direct mechanism has greatly improved the response rate of the patients with steatosis included, this parameter not being so important in predicting the response to treatment, but rather a prognostic factor for other comorbidities: accelerated atherosclerosis, cirrhosis or hepatocellular carcinoma (11, 12).

Thus, referring to the long-term negative potential of steatosis, we considered it necessary to evaluate its severity in our study patients. Over half of the patients enrolled in the study had moderate-severe steatosis grade S $\geq$2 (54% of the total).

The group of patients with steatosis grade S3 was the most numerous (25.7%), followed by grade S2 (23.9%), the smallest number of patients presenting steatosis grade S2-3 (4.4%). Only 10 of the total 113 patients showed no evidence of steatosis by Fibromax (S0), while 9 had steatosis grade S0-1, suggesting an incipient steatosis. Thus, there is an increased prevalence of moderate-severe steatosis in HCV genotype 1b patients, as opposed to other studies that rather highlight the involvement of genotype 3 in these advanced steatosis forms (moderate-severe in 40-50% of cases), and less of genotypes 1 or 4, with the presence of moderate-severe steatosis in only 10-15% of cases (11).

Another important aspect was the interpretation of the correlation between the initial viral load and steatosis grade. A significant correlation ($p = 0.048$) was found between steatosis grade and viral load, so that patients with steatosis S0 had a mean viral load of 582,450 IU/mL, significantly lower than that of patients with steatosis S3, with a viral load of 1,613,050 IU/mL. Considering that all our patients had HCV genotype 1b, these data are somewhat contradictory to those obtained by other international studies that have demonstrated the direct correlation between steatosis grade and baseline viral load in case of genotype 3 rather than in genotype 1 (13). Thus, Jackel-Cram investigated the effects of HCV 3a core protein compared to HCV 1b core on fatty acid synthase (involved in de novo synthesis of AG) and revealed a higher prevalence as well as an increased severity of steatosis in the case of genotype 3a compared to 1b (13).

However, a study by Kara (14) also highlights the direct relationship between HCV genotype 1 infection and the presence of steatosis in 82% of patients in the absence of any additional risk factors for this histopathological change. This study also demonstrated a significant link between initial viral load and steatosis grade, similar in relevance to the results of our study ($p = 0.02$ *vs.* $p = 0.048$)

Another interesting aspect in our study was the significant correlation between the high AFP level and grade of steatosis in patients with chronic HCV infection. Thus, in patients without steatosis, mean AFP level was 5.37 IU/mL, compared to 30.82 IU/mL in patients with steatosis S3 ($p = 0.018$). Similar results have been reported

by many other studies, such as that conducted by Mousa et al. (15), which compared two groups of patients (50 patients with steatosis, 50 without steatosis) and showed a significantly higher AFP level in patients with steatosis ($p < 0.01$) In other studies are highlighted the clear association ($p < 0.05$) of elevated AFP levels not only with hepatic steatosis, but also with elevated levels of uric acid, fasting blood glucose, vitamin D deficit and AST (16, 17, 18).

CONCLUSIONS

In North-eastern Romania, we found an increased prevalence of advanced steatosis in HCV genotype 1b infected cirrhotic patients, correlated with the presence of cardiovascular, renal and metabolic comorbidities in over 30% of cases. However, the sustained virologic response was very good (approximately 100%), with the normalization of cytolytic enzymes and platelets in significant percentages. We have found a significant correlation between the advanced grade of hepatic steatosis and the level of hepatic cytolytic enzymes and GGT both before the initiation of therapy and at its completion. This finding pleads for the need to reduce the steatosis grade prior to antiviral therapy to limit the level of hepatic cytolysis that would predispose to a more rapid progression to complications even in those who attained sustained virological response.

MAASTRICHT V: BEST EVIDENCE AND RELEVANCE TO THE MANAGEMENT OF HELICOBACTER PYLORI INFECTIONS

The Maastricht conference first took the initiative in 1996 and since then has been repeated at intervals of 4–5 years. Experts invited were chosen for their expertise and contribution to *H pylori* research and/or guideline methodology to review and discuss all relevant clinical data to arrive at recommendations for the clinical management of *H pylori* infection. It has been made important progress in the management of *Helicobacter pylori* infection in this fifth edition of the Maastricht Consensus Report. Key aspects related to the clinical role of *H. pylori*, to the increasing H. pylori resistance to previously efficacious antibiotic regimens, to the feasibility and efficacy of gastric cancer prevention, to the recommendation of treatment of all *H. pylori* infected subjects, to the perspective of potential interactions with other microbiota were re-evaluated. The aim of this report is to serve as a state-of-the-art guide for the management of *H. pylori* infection (Malfertheiner P, Megraud F, O'Morain CA, Gisbert JP, Kuipers EJ, Axon AT, Bazzoli F,Gasbarrini A , Atherton J, Graham DY, Hunt R, Moayyedi P, Rokkas T, Rugge M, Selgrad M, Suerbaum S, Sugano K, El-Omar EM , European Helicobacter and Microbiota Study Group and Consensus panel. Management of *Helicobacter pylori* infection-the Maastricht V/Florence Consensus Report. *Gut* 2017; 66(1): 6-30).

Department of Medical Specialties (II)

ACUTE GOUT ATTACK WITH NORMAL SERUM URIC ACID LEVELS (Abstract): **Aim:** The paper aims to determine the prevalence of clinical cases with acute gout attacks and normal serum uric acid levels. **Material and methods:** This retrospective study was conducted between October, 2013 and June, 2014 in 30 patients diagnosed with acute gout attack admitted to the Ist Clinic of Rheumatology of Iaşi. The diagnosis was based on clinical manifestations and positive response to therapeutic test with colchicine. **Results:** Normal serum uric acid levels were found in 63.3% of the patients with acute gout attack. The inflammatory syndrome was detected in 76.6% of patients with high erythrocyte sedimentation rate (ESR) levels and in 30% of patients who had elevated C-reactive protein levels. The urinary excretion of uric acid was measured in 11 patients and it was found increased in 55% of them. **Conclusions:** The diagnosis of acute gout attack should not be excluded in the presence of normal serum uric acid levels if the clinical manifestations or the positive response at colchicine are suggestive of gout. The low uric acid level is correlated with increased inflammatory factors and urinary excretion of uric acid. **Keywords:** ATTACK, GOUT, URIC ACID, PCR, COLCHICINE

Described since antiquity and named by Hippocrates the "disease of kings and queen of diseases", emphasizing the importance of overeating and heredity in the pathogenesis of this disease, gout is today known as an inflammatory arthritis caused by an abnormality of purine metabolism. The prevalence of this disease is 0.16 to 1.36%, with higher rates among men (male: female ratio = 2-7: 1) and a mean age of onset of 50 years. The natural history of this inflammatory arthritis has four stages: asymptomatic hyperuricemia, acute gouty arthritis, intercritical phase and chronic tophaceous gout. In asymptomatic hyperuricemia high blood uric acid levels are not accompanied by clinical manifestations, which occur during acute attacks of gout. Intercritical phase is by definition asymptomatic with a variable time between gout attacks and chronic tophaceous gout is the advanced stage of this disease characterized by accumulation of urate crystals in tissues and formation of tophi (1, 2, 3).

Clinical expression of gout is the appearance of inflammatory symptoms predominantly in the metatarsophalangeal joint of the big toe, which can then affect other joints such as the ankle, knee, wrist and small joints of the hands. From a biological perspective, hyperuricemia (uric acid > 7 mg /dl) forms a part of diagnostic criteria in gout, although only one fifth of the patients with increased uric acid levels become symptomatic (1,4). The presence of inflammatory syndrome (high ESR, C-reactive

protein, and fibrinogen) and radiological changes (swelling of soft tissues in the early stages reaching erosions, "blown bone" appearance, tophi in advanced stages) suggest a diagnosis of gout. The laboratory tests for determining the urinary uric acid excretion are also discussed as they establish the type of excretion (hyperexcretion or normal excretion) important to know when choosing the hypouricemiant treatment (5). The correct diagnosis can be made only by demonstration of uric acid crystals in the synovial fluid of the joint. These crystals have an acicular appearance under optical microscope and negatively birefringent on polarizing examination (6, 7).

This study aimed to determine the prevalence of acute gout attack cases with normal serum uric acid levels, considering that data in the literature suggest that at least 10% of patients with acute gouty arthritis are normouricemic.

MATERIAL AND METHODS

We present a retrospective study conducted between October 2013 - June 2014 including 30 patients admitted to and diagnosed with acute gout attack in the Ist Rheumatology Clinic of Iasi/Rehabilitation Hospital. The diagnosis was made based on both clinical manifestations and favorable response to colchicine administration (therapeutic trial).

RESULTS

Of the 30 patients 25 (83.3%) were males and 5 (16.6%) females (fig. 1); mean age was 64.3 years (range 44-82 years). It is important to note that the age at the onset of gout attacks in men was younger in our study (44 years) than in the cases reported in the literature (50 years). Analyzing the home treatment in our patients, we found that only 4 (13.3%) were on different doses of allopurinol prior to admission.

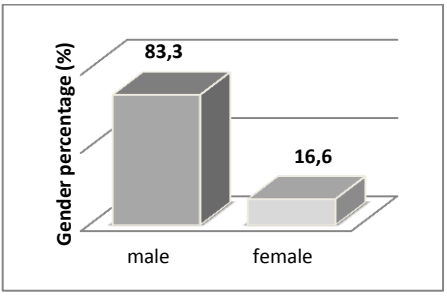

Fig. 1. Patient distribution by gender

The serum uric acid levels among the study patients was within normal range in 19 cases (63.3%) and elevated in 11 cases (36.6%) (fig.2). The inflammatory syndrome was present in most cases: elevated ESR and C-reactive protein were found in 76.6% and 30% of the cases, respectively (fig. 3). From this point of view, the limitation was the fact that C-reactive protein was not measured in all cases.

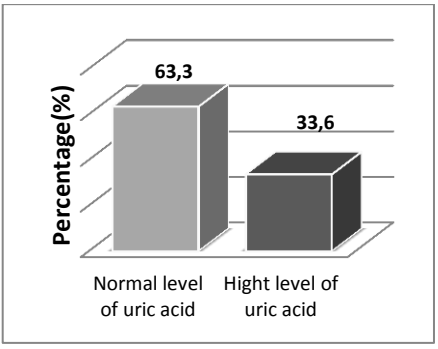

Fig. 2. Concentration of uric acid

In 11 of the 30 study patients the 24-hour urinary uric acid excretion was determined. It is known that this investigation gives us information on the hyper- or normo secretor status of the patient, which helps in selecting the therapeutic approach. The results showed that 55% of the 11

cases had increased levels of renal uric acid excretion.

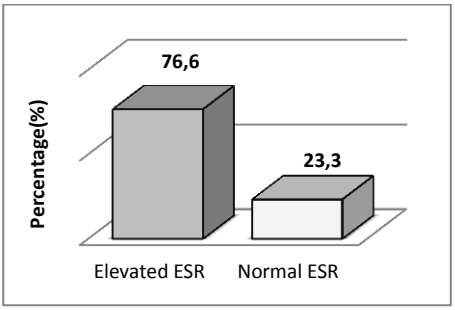

Fig. 3. Inflammatory syndrome

DISCUSSION

According to literature data, normal serum uric acid levels can be found in at least 10% of patients with acute gout attack; however, some studies show a proportion close to 50% of patients. A normal amount of uric acid during an acute gout attack can be explained by the increased urinary uric acid excretion resulting from ACTH release followed by adrenal stimulation caused by the stress of the painful process (1, 4, 5). Inflammation plays an important role in acute gout attack as it is believed that increased levels of inflammation markers (ESR, CRP), and IL6 and IL1β are directly correlated with lower serum uric acid levels (5).

An important aspect is the correct diagnosis, especially in elderly patients where symptoms can be intricate with a number of other co morbidities. A differential diagnosis of osteoarticular pains is required, as they can be of many causes, such as arthritis, multiple myeloma, autoimmune diseases (rheumatoid arthritis, systemic lupus erythematosus), bursitis, tendonitis and not the least gout. Elderly patients require a more detailed history not to miss a possible equivalence of angina pain (8). Also, the treatment of gout in elderly can be challenging in part because of increased colchicine and nonsteroidal antiinflammatory drug toxicity and low compliance to treatment and diet (9).

CONCLUSIONS

In our study we highlighted the fact that normal serum uric acid is not a criterion for exclusion of the diagnosis of acute gout attack, especially in the presence of a suggestive clinical picture or therapeutic response to colchicine. Low uric acid levels may be related in direct proportion to the elevated acute phase reactants as well as increased renal uric acid excretion.

ROSAI - DORFMAN DISEASE – A RARE CAUSE OF CERVICAL LYMPHADENOPATHY

Rosai-Dorfman Disease is a rare histiocytic disorder affecting various groups of lymphnodes in the human body. Rosai and Dorfman in 1969 described this disorder under the term Sinus Histiocytosis with Massive Lymphadenopathy. Majority of patients are children or young adults. Males are more commonly affected. Cervical Lymphnodes are commonly affected; however other lymphnodal groups like axillary, inguinal and mediastinal may also be involved. Extra-nodal involvement is seen in 25-40% cases. Various extranodal sites have been reported including the upper respiratory tract, gastrointestinal tract, paranasal sinuses, orbit and even meninges. In most of the cases patients are usually asyptomatic except for cervical lymphadenopathy however they may present with symptoms due to extranodal involvement and infiltration of vital organs. The disease usually has a self limiting, benign course and may not need any treatment. Episodes of remissions and exacerbations are characteristic however few patients may die from their disease. Etiology is not exactly known however like any other histiocytic disorder responds well to systemic steroids. Histologically it is characterised by pericapsular fibrosis with dilated sinuses, heavily infiltrated by large hitiocytes, lymphocytes and plasma cells. Emperipolesis is characteristic of lymphnodal involvement. Poor prognosis in the disease is due to wide spread dissemination and involvement of vital organs like kidney and liver or presence of immunological abnormalities. Otherwise the disease has a very stable and benign course. Diagnosis of Rosai-Dorfman disease is based on clinical suspicion and histopathological confirmation. Histologically there is infiltration of the tissue by lymphocytes, histiocytes and plasma cells. Demontration of emperipolesis i.e.engulfment of lymphocytes and erythrocytes by histiocytes, is usually diagnostic of Rosai-Dorfman Disease. Immunohistochemistry is usually necessary for confirmation of diagnosis. Characteristically S100 is always positive. Also some other markers like CD68, CD163, α1 antichymotrypsin and α1 antitrypsin may also be positive (2). Systemic symptoms in this disease may be related to enhanced production of such cytokines (5). In general the disease has a benign course and is self limiting. However massive lymphadenopathy and multisystemic involvement, especially vital organs like CNS, Liver, Kidney and lungs is usually associated with poorer prognosis. The treatment in Rosai-Dorfman Disease is non-specific and depends on the site of involvement. Isolated Lymphadenopathy may not be treated at all except for cosmetic reasons. However if any vital organs are involved or if the lesion is causing some obstructive symptoms or pressure symptoms, aggressive treatment may be indicated. In conclusion, Rosai-Dorfman Disease should be kept as a diffential diagnosis in young patients presenting with massive cervical lymphadenopathy. High degree of clinical suspicion with typical histopathological features and immunohistochemistry are diagnostic. These patients respond well to systemic steroids and aggressive surgical treatment is needed only in life threatening complications. However it is necessary that both clinicians and pathologist keep this entity in their list of differential diagnosis for massive lymphadenopathy (Shelkar R,. Ekhar VR, Rane S, et al. Rosai - Dorfman Disease – A Rare Cause of Cervical Lymphadenopathy. *MedPulse – International Medical Journal,* 2014; (2): 50-52).

INFLAMMATORY MARKERS IN HYPERTENSIVE PATIENTS AND INFLUENCE OF SOME ASSOCIATED METABOLIC RISK FACTORS (Abstract): Some epidemiological studies have begun to show a possible correlation between systemic and vascular inflammation and the presence of essential hypertension, especially if it is associated with metabolic risk factors (obesity, dyslipidemia, diabetes mellitus). **Objectives:** The objective of this study was to evaluate the levels of C-reactive protein and fibrinogen as markers of inflammation in patients with essential hypertension, with or without associated metabolic risk factors. **Material and methods**: The retrospective study included 200 patients separated into five groups (control, hypertension, and respectively hypertension associated with obesity, or diabetes mellitus type II non-obese or obese type II diabetes). Anamnestic and anthropometric data, blood pressure and heart rate, blood glucose, lipid profile, fibrinogen, quantitative C-reactive protein and echocardiographic parameters have been reported and compared between groups. **Results:** Our study evaluated a total of 110 women and 90 men, each of the five groups comprising a total of 22 (55%) women and 18 (45%) males. Study of the inflammatory syndrome found the highest values of CRP in hypertensive and obese patients: 1.56 ± 3.08 ($p = 0.014$) in group 3 and 0.92 ± 1.11 ($p = 0.001$) in group 5 versus control group (0.30 ± 0.36). Fibrinogen values were significantly elevated in all groups of hypertensive, demonstrating the existence of an inflammatory syndrome, even in the absence of obesity or diabetes. **Conclusions:** All the patients showed a statistically significant relationship between elevated CRP and fibrinogen levels and the presence of hypertension, isolated, or in combination with obesity and diabetes mellitus. **Keywords**: C-REACTIVE PROTEIN, FIBRINOGEN, ESSENTIAL HYPERTENSION, METABOLIC RISK FACTORS.

Atherosclerosis is a pathological condition, caused by cardiovascular risk factors, which are associated to systemic and vascular inflammation. Observational studies have shown consistently that blood levels of systemic markers of inflammation is correlated with the risk of atherosclerosis. The association between C-reactive protein (CRP) and coronary heart disease has been the most intensively studied. Experimental studies indicated that atherosclerosis is not only a disorder of lipid accumulation, but

also a chronic inflammatory process (1, 2, 3). Inflammation plays an important role in atherothrombosis and measurement of inflammatory markers such as high sensitive CRP may be a new method for detecting individuals at high risk of plaque rupture. Several large prospective studies have shown that high-sensitive CRP is a strong independent predictor of future myocardial infarction and stroke in apparently healthy people, but with cardiovascular risk factors. Recent information about the CRP involvement in pathogenesis of atherosclerotic plaque, correlated with endothelial dysfunction, and having a direct role in molecular expression of cell adhesion, offer the possibility that CRP is also a potential therapeutic target. Thus, researchers have proposed that inflammatory markers such as CRP may be additional factors to assess global cardiovascular risk (1, 2, 3).

Hypertension is a major risk factor for developing atherosclerosis and its high prevalence (44% at the population level in Europe) will prone to many complications (4). In population studies, CRP was noted as a marker of inflammation that may enhance the risk of developing hypertension, not only the acceleration of atherosclerosis (1). In a prospective observational study, it was demonstrated the existence of higher values of CRP in individuals with high blood pressure. It is believed that the levels of CRP could increase blood pressure by reducing nitric oxide production in endothelial cells, resulting in vasoconstriction and increased production of endothelin-1. The CRP may also function as proatherosclerotic factor, by increasing the expression of the angiotensin receptor 1 (5). The inflammation has been shown to be correlated with the renin-angiotensin-aldosterone system (RAAS). Inflammation associated with oxidative stress and activation of the RAAS contributes to increased morbidity and mortality (6).

However, studies evaluating systemic inflammation and hypertension are still scarce and due to frequently associated risk factors (obesity, dyslipidemia, impaired glucose metabolism), the direct influence of elevated blood pressure was less evident in these studies. In this respect, our study aimed to assess the level of fibrinogen and CRP differentiating patients hypertensive only from those with associated risk factors.

MATERIAL AND METHODS

We conducted a retrospective study (between 01.07.2011 - 30.06.2013) which included 200 patients diagnosed with essential hypertension, hospitalized in the Cardiovascular Clinic, from Rehabilitation Clinical Hospital in Iaşi. At inclusion, patients were divided into five groups of 40 individuals, matched for age and gender, various by the association of metabolic risk factors as follows: group 1 (control group, after evaluation, hypertension and associated risk factors were excluded); group 2 (patients with hypertension, body mass index - BMI normal, without glucose metabolism disorders); group 3 (patients with hypertension and obesity, without glucose metabolism disorders); group 4 (patients with hypertension and non-obese type II diabetes); group 5 (patients with hypertension and obese type II diabetes). We excluded patients with recent infection or those with known inflammatory disease, diabetics with severe complications, patients with a history of cardiovascular disease (myocardial ischemia evidenced by electrocardiogram, heart attack or stroke), neoplasia, mental disorders, hepatic or renal failure. Also, in order to achieve ho-

mogeneity between groups, at the creation of the database, patients were evaluated with regard to the treatment scheme: for the treatment of hypertension and diabetes mellitus patients received drug treatment, but we excluded diabetic patients on insulin therapy and patients on the lipid-lowering treatment, regardless of class, knowing some antiinflammatory pleiotropic effects of hypolipemic drugs (7, 8).

Data reported and evaluated included: age, gender, anthropometric data (BMI, abdominal circumference - AC, obesity was defined by a BMI $\geq$ 30 kg/m^2), systolic blood pressure (SBP) and diastolic blood pressure (DBP) measured in supine using aneroid sphygmomanometers and heart rate. Biological evaluation included determination of inflammatory markers (CRP was determined quantitatively with latex immunoturbidimetric method by nephelometry, with normal range <1 mg/l and fibrinogen with koagulometers Clauss method, normal range 200-400 mg%) and metabolic parameters by the spectophotometric method (fasting plasma glucose, total cholesterol, HDL-cholesterol, LDL-cholesterol, triglycerides). By transthoracic echocardiography were measured cardiac cavities, interventricular septum, posterior wall and left ventricle ejection fraction for assessing systolic function and left ventricular hypertrophy.

Statistical analysis of data was performed with SPSS version 17 and Statistics Microsoft Office Excel 2007. Chi square test and Student's t-test were used for means and frequency analysis, considering the level of significance for p value < 0,05.

RESULTS AND DISCUSSION

This study included 200 patients with a mean age of 60.37 ± 8.47 years and age limits between 40 and 79 years. The study evaluated a total of 110 women and 90 men, each of the five groups comprising a total of 22 (55%) women and 18 (45%) males. Study groups were homogeneous for age and gender. Among the variables studied, lipid profile was modified by the presence of other risk factors in hypertensive patients. Total cholesterol was 183 ± 17 values in the control group versus 207.6 ± 40, 5 (p = 0.001) in group 2, 197.8 ± 28.6 (p = 0.007) in group 3, 188.5 ± 40.4 (p = 0.437) in group 4 and 200.9 ± 33.94 (p = 0.004) in group 5. Except enrolled patients in group 4, the remaining hypertensive had significantly elevated cholesterol values. Evaluation of triglyceride levels showed the highest values in patients with hypertension and diabetes: 104 ± 36.8 in the control group, versus 121.8 ± 56.3 (p = 0.1) in group 2, 159.1 ± 96.7 (p = 0.001) in group 3, 168.5 ± 107.8 (p = 0.001) in group 4 and 155.7 ± 58.9 (p < 0,001) in group 5. Cholesterol levels were significantly increased in hypertensive patients, even in the absence of obesity or diabetes. These data are consistent with other studies in the literature showing the importance of dyslipidemia, in particular hypercholesterolemia, as a predictor of the installation of arterial hypertension and its complications (9). Some studies indicated also the presence of lipoprotein (a) in a greater proportion in hypertensive patients (10). Current medical guidelines highlights the significant increase in cardiovascular risk in hypertensive and dyslipidemic patients and recommend that LDL-cholesterol and even triglycerides should be maintained at levels below 100 mg/dl (11, 12). Atherogenic dyslipidemia determines maintenance of endothelial dysfunction (13), and the vascular prothrombotic status (14).

Study of the inflammatory syndrome found the highest values of CRP in hypertensive and obese patients: 1.56 ± 3.08 (p = 0.014) in group 3 and 0.92 ± 1.11 (p = 0.001) in group 5 versus control group (0.30 ± 0.36) (tab. I).

TABLE I
CRP in the study groups

CRP	Control group	Group 2	Group 3	Group 4	Group 5
Mean ± SD	0.30 ± 0,36	0.37 ± 0.42	1.56 ± 3.08	0.69 ± 1.16	0.92 ± 1.11
p	-	0.424	0.014	0.045	0.001

Fibrinogen values were significantly elevated in all groups of hypertensive, compared with the control group, demonstrating the existence of an inflammatory syndrome associated with hypertension, even in the absence of obesity or diabetes (tab. II).

TABLE II
Fibrinogen in the study groups

Fibrinogen	Control group	Group 2	Group 3	Group 4	Group 5
Mean ± SD	288.6 ± 53.09	319.5 ± 79.9	363.3 ± 144.4	326.0 ± 84.7	354.02 ± 85.2
p	-	0.046	0.004	0.021	0.001

Statistical analysis showed that, in the absence of obesity, diabetes should not influence as much CRP, compared with the presence of BMI change. Echocardiographic parameters of left ventricular hypertrophy were significantly higher in hypertensive patients with and without obesity.

In epidemiological studies, elevated CRP levels were consistently predictive of cardiovascular disease in different populations. Moreover, sensitive tests of CRP biological properties (such as half-life period of biological stability) make this protein to be a useful clinical marker of subclinical chronic inflammation (15, 16). Oxidative stress and inflammation have a central role in the pathogenesis of atherosclerosis. Reactive oxygen species, including superoxide and hydrogen peroxide, modify low-density lipoprotein to a vascular form of oxidized low-density lipoprotein. LDL stimulates endothelial cells to express leukocyte and vascular adhesion molecules, leading to the recruitment of monocytes and T lymphocytes, which invade the intima. Inflammation also triggers a cascade that leads to fibrosis and vascular remodeling (6). In our study, fibrinogen was a marker of inflammation in all types of hypertension, indicating that the inflammatory process accompanies early other cardiovascular risk factors, in order to achieve vascular complications. In a very recent study Hong L, et al. (17) demonstrated the relationship between fibrinogen levels and severity of coronary lesions, angiographycally proven, in patients with coronary heart disease and type II diabetes.

Recent observations on the immune response and hypertension have shown that, like many inflammatory stimuli, hypertension has a double effect: one is to promote T cell activation, and the second is to in-

crease the expression of chemokines and adhesion molecules in the target tissues to help access of the activated inflammatory cells to the tissue (18). Based on studies conducted by Harrison (18) or Pauletto (19), it was highlighted the hypothesis that hypertension causes accumulation of activated T cells in the perivascular "fat" and kidney. In these places, these cells release cytokines that affect adjacent vascular cells and renal tubular epithelium. According to this concept, many recent studies support the idea that the cytokines produced by T cells and other inflammatory cells contribute to hypertension installation. Some cross-sectional studies have shown elevated levels of CRP, TNF-α, amyloid-A in subjects with prehypertension and before the target organ lesions (20).

CONCLUSIONS

In the studied groups, we found a trend of increase in inflammatory markers in relation to the presence of hypertension. Both sexes showed a statistically significant relationship between elevated CRP and fibrinogen levels and the presence of hypertension, isolated, or in combination with obesity, which confirms that hypertensive patients present a proinflammatory and procoagulant status, which implies an increased risk of cardiovascular disease. Obese patients with hypertension and diabetes had significantly higher values of total cholesterol and triglycerides. There is a significant trend of dyslipidemia, with increased BMI and abdominal obesity, associated with high blood pressure and determining an increased risk of developing atherosclerosis.

CLINICAL RESULTS OF LINEZOLID IN ARTHROPLASTY AND TRAUMA MRSA RELATED INFECTIONS

Infections encountered in trauma surgery and implant related infection in arthroplasty, present a complex therapeutic challenge. Gram-positive organisms, particularly staphylococci and streptococci, are responsible for the majority of these infections encountered in orthopaedic practice in the United Kingdom and United States. Although the efficacy of linezolid has been well demonstrated in nosocomial pneumonia, bacteraemia, skin and soft tissue infections there is limited data supporting its use in complex orthopaedic infections. Using a retrospective analysis of twenty-two patients with orthopaedic related infections receiving a course of linezolid, the authors Joel J. and collaborators demonstrates that linezolid delivers excellent oral bioavailability, with good penetration into bone, joints and soft tissue. It exhibits action against gram-positive organisms, including methicillin resistant Staphylococcus aureus and vancomycin resistant enterococci, and it is ideally suited for the variety of infections encountered in orthopaedic practice and used in conjunction with surgical management, excellent results can be achieved in resolving infection. (Joel J, Graham SM, Peckham-Cooper A et al. Clinical results of linezolid in arthroplasty and trauma MRSA related infections. *World J Orthop*. 2014 Apr 18;5(2):151-7. PMID:248 29878)

VITAMIN D STATUS IN PATIENTS ADMITTED IN A CLINIC OF ENDOCRINOLOGY (Abstract)**:** Vitamin D deficiency has been known as a global health problem and there were reported moderate to strong inverse associations between 25(OH) D concentrations and cardiovascular diseases, serum lipid concentrations, inflammation, glucose metabolism disorders, weight gain, infectious diseases, multiple sclerosis, mood disorders, declining cognitive function, impaired physical functioning, and all-cause mortality. In Romania there are only a few published reports on vitamin D status among adult population**. Aim:** To evaluate vitamin D status in 440 patients those were admitted in our clinic for various endocrine pathology**. Material and method:** Serum 25-hydroxy vitamin D was measured using chemiluminescence assay. We categorized the vitamin D levels in 3 subgroups (deficiency, insufficiency and sufficiency)**. Results:** In our study there was a high prevalence of both vitamin D deficiency and insufficiency, while optimal level was observed only in a very small number of patients. **Conclusions:** We demonstrated a high frequency of vitamin D deficiency in general population, especially in elderly and children. There are still many controversies regarding the optimal vitamin D status and the supplementation dosage, so long term large scale studies are needed regarding efficacy and safety. **Keywords:** VITAMIN D, OSTEOPOROSIS, PHOSPHO-CALCIC METABOLISM.

Vitamin D was long known to be essential in bone metabolism, and its main function is the regulation of calcium and phosphate homeostasis, in conjunction with PTH, the gut, kidney and bone being the principal target tissues. Vitamin D deficiency has been recognized as a pandemic with various health consequences (1). Low vitamin D status has been associated with an increased risk of type 1 diabetes mellitus, cardiovascular disease, certain cancers, cognitive decline, depression, pregnancy complications, autoimmunity and allergy (2, 3)**.**

Vitamin D is a hormone precursor that is present in 2 forms: vitamin D2 (ergocalciferol) and vitamin D3 (chole-calciferol). Both are produced by photolysis from naturally occurring sterol precursors. Vitamin D can be manufactured in the skin by way

of ultraviolet B rays. There is very little vitamin D production from November to May throughout Europe. Also, we expose less than 5% of our skin to the sun and the vitamin D production in the skin decreases 4 times with age. Very few foods in nature contain vitamin D. The flesh of fatty fish (such as salmon, tuna, and mackerel) and fish liver oils are among the best sources. Small amounts of vitamin D are found in beef liver, cheese, and egg yolks. The major pathologic complication of vitamin D deficiency is rickets (in children) or osteomalacia (in adults), which results mainly from the deficiency of calcium and phosphate required for bone mineralization. A low vitamin D level is an established risk factor for osteoporosis and increasingly recognized as an important factor in fall status among elderly patients (tab. I).

TABLE I

Vitamin D levels and their impact on bone health

Definition (vitamin D)	Serum 25(OH)D level	Impact on bone health
Deficiency	< 25 nmol/L(< 10ng/mL)	Mineralization defect
Insufficiency	< 50 nmol/L(< 20 ng/mL)	Increased bone turnover and/or PTH
Sufficiency	50-75 nmol/L (20-30 ng/mL)	Neutral effect (bone turnover and PTH normalized), desirable benefits on fracture, falls and mortality
Sufficiency	> 75 nmol/L(> 30 ng/mL)	Desirable target in the fragile elderly due to optimal benefits on fracture, falls and mortality
Upper limit of adequacy	125 nmol/L	Possibility of adverse effects above this level

Vitamin D insufficiency is widespread (4), and is present in every region of the world, with a prevalence of 63.9% global and 57.7% in Europe (5). The rates of vitamin D deficiency are highest in the Middle East and South Asia (6). In elderly populations in Europe, vitamin D insufficiency is more common in the south than in the north, and more likely in women than in men (7).

In Romanian postmenopausal women, the mean concentrations of 25(OH)D were 20 ng/mL (50 nmol/L) and the prevalence of vitamin D deficiency was 32% (8), while in institutionalized seniors, we reported that mean concentrations of 25(OH)D were 28.5±10.8 nmol/L (9), far below the minimum 50 nmol/L that the Institutes of Medicine have set for everyone in the population. Our first study demonstrated 17,14% severe deficiency of 25(OH)D (10).

MATERIAL AND METHODS

Our study included 440 patients referred to us for different endocrine problems and was conducted in the Endocrinology Clinic of Saint Spiridon Hospital in Iasi from January 2013 till March 2014. The patients' ages ranged from 4 to 87 years. To determine vitamin D status we measured serum 25-hydroxyvitamin D3 (25-OH D3) by taking a single blood sample in the morning, in a fasting stage. Serum 25-OH D3 was measured by chemiluminescence assay with minimum detection limit of 3.0 ng/mL.

As seen in table I, we categorized vitamin D levels in 3 subgroups, based on the most recent studies – deficiency (< 10

ng/mL); - insufficiency (10-20 ng/mL) and sufficiency (> 20ng/mL)(11).

RESULTS AND DISCUSSION

The distribution by age was various, with the majority of patients (53%) in the 50-70 years group, followed by 13% (4-18 years and over 70), 9% (30-40 years), 7% (40-50 years) and 5% (18-30 years) (fig 1). The mean (SD) serum 25OHD was 17.21 ng/mL, with 242 patients in the insufficiency group (fig. 2). We found a high prevalence of both vitamin D deficiency (25OHD < 10 ng/mL) -16% and insufficiency (25OHD=10-20 ng/mL) -55 % (fig 2).

In our study, vitamin D deficiency (<10 ng/mL) was observed in:

- 15% postmenopausal women;
- 18% patients with osteoporosis;
- 7% children and adolescents.

Vitamin D insufficiency (10-20 ng/mL) was found in:

- 54% postmenopausal women;
- 63% osteoporotic patients;
- 54% children and adolescents.

39% of children and adolescents presented vitamin D levels of 20-30 ng/mL but none of them had vitamin D sufficient levels (>30ng/mL).

Vitamin D sufficiency (> 30 ng/mL) was observed only at 12% of all studied patients.

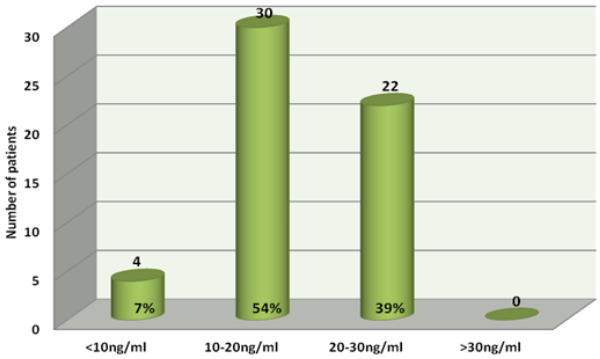

Fig. 5. Vitamin D in children and adolescents (4-18 years)

There are many controversies regarding the definition of different categories of low vitamin D and of the precise estimation of optimal vitamin D status (usually, in Europe a threshold of 20 ng/mL is agreed, although in the USA a 30 ng/mL is favored). In our country, dietary sources of vitamin D are scarce and there is no fortification of food with vitamin D. After giving bread fortified with 5000 IU (125 mcg) to nursing home residents, the medium 25(OH)D seric concentration were significantly higher after 3, 6 and 12 months (12). Another study measured the bone mineral density (BMD) before and after 12 months of serving bread fortified with 800 mg calcium carbonate and 5000 IU vitamin D to nursing home residents. After 1 year the hip BMD grew with 24 % of the initial value (13).

The greatest risk for bone and several major human diseases and preventable human health conditions are associated with 25OHD levels below 20 ng/mL (or 50 nmol/L).

The mean or median level of 25OHD around the world hardly exceeds 20 ng/mL (50 nmol/l) with slightly higher levels in US Caucasians (NHANES data) (14). An estimated number of at least 1 billion (and probably many more) people around the world have 25OHD levels < 20 ng/mL (50 nmol/l), so that their bone health could be improved by vitamin D supplements that

bring their 25OHD level above 20 ng/mL (50nmol/l). Several authoritative meta-analyses indicate that a daily dietary vitamin D supplementation (600-800 IU D3) plus calcium reduces the risk of fractures and falls. Such vitamin D dose is likely to increase mean 25OHD levels by 6-16 ng/mL (15-40 nmol/L) and bring serum 25OHD to ≥ 20 ng/mL (> 50 nmol/L) in most subjects. It is no unlikely that even higher vitamin D supplements, bringing 25OHD levels to over 30 ng/mL (75nmol/L) may convey further benefits without creating additional risk. This would however require vitamin D supplements ≥ 2,000 IU D3 per day for millions, if not billions of people, and until the completion of long term large scale RCTs the efficacy and safety of such interventions cannot be assured for the general population. Vitamin D supplementation (600-800 IU D3) plus calcium should be considered in elderly people (older than 75 years) with an increased fracture and/or fall risk, in particular people living in nursing homes. A Romanian study showed that after giving 200,000 IU Vitamin D 3 every 4 months for one year period, the 25(OH)D concentration grew 102%, but still didn't reach optimal range (> 75 nmol/L)(15).

CONCLUSIONS

Our study confirms the pre-existing data in literature and is showing once more that only a small number of patients are in the safe range regarding vitamin D, the majority of patients being in the deficiency or insufficiency area. 20 ng/mL should be the minimal serum 25-OHD concentration at the population level and in patients with osteoporosis to ensure optimal bone health, all individuals below this threshold requiring vitamin D supplementation. Since in our country we have only a few published reports on vitamin D status, we need long term large scale studies regarding the efficacy and safety of the vitamin D supplementation.

GASTROINTESTINAL STROMAL TUMOURS: FROM KIT TO SUCCINATE DEHYDROGENASE

Gastrointestinal stromal tumour (GIST) is the most common mesenchymal neoplasm of the gastrointestinal tract, with a worldwide annual incidence of 11–18 per million. The clinical behaviour of GIST is variable, ranging from entirely benign to highly aggressive. Several factors can aid in the stratification of the risk of malignant behaviour for GIST, including anatomical location, tumour size, mitotic activity, and genotype. Approximately 80% of GISTs harbor oncogenic mutations in KIT, and 8–10% harbor oncogenic mutations in PDGFRA, which encode tyrosine kinase receptors. The discovery of these mutations has served as an excellent model for the development of effective molecularly targeted therapies for solid tumours. Specific genotypes, in part, predict the response to treatment with the tyrosine kinase inhibitors imatinib and sunitinib. However, ~10% of GISTs lack KIT and PDGFRA mutations (often referred to as 'wild-type' GISTs); such tumours are generally resistant to imatinib therapy. Recent insights into the biology of 'wild-type' GISTs have resulted in clinically significant subclassification of this heterogeneous group of tumours, a large subset of which are now known to represent succinate dehydrogenase-deficient GISTs. Recognition of this distinctive class of tumours has critical implications for prognosis, therapy, clinical follow-up, and genetic counselling. This review provides an update on the diagnosis and pathogenesis of these less common classes of GISTs, summarizes the clinical and pathological features associated with particular genotypes, and discusses mechanisms of resistance to targeted therapies. (Leona A Doyle & Jason L Hornick. Gastrointestinal stromal tumours: from KIT to succinate dehydrogenase. *Histopathology* 2014; 64: 53–67)

1. Ph.D. Student
2. Department of Internal Medicine I

PREDICTIVE VALUE OF A POSITIVE EXERCISE STRESS TESTING AND CORRELATIONS WITH CARDIOVASCULAR RISK FACTORS (Abstract): Electrocardiogram exercise stress test (EST) is a widespread technique in assessment of coronary artery disease, stratifying cardiovascular risk and prognosis. **Aim**: Evaluation of the impact of cardiovascular risk factors upon the results of EST. **Methods**: The 2-year retrospective study included 294 patients referred to an EST. All patients were assessed according to: presence of typical angina chest pain at admission, medical history of angina or myocardial infarction, resting electrocardiogram, global ejection fraction at echocardiographic exam and traditional cardiovascular risk factors. We compared the results between two groups: positive and negative EST. **Results**: The patients were age- and sex-matched. 160 patients (54.42%) had a positive EST. Positive EST was associated with typical angina chest pain at admission (88.12% vs. 76.11%, p=0.008), coronary artery disease history (61.87% vs. 41.04%, p=0.0003), resting ECG abnormalities (49.37% vs. 36.56%, p=0.026), arterial hypertension (85.62% vs. 74.62%, p=0.019). Ejection fraction was higher in the negative EST group (63.34±8.57% vs. 61.18±11.34%, p=0.035). Type 2 diabetes mellitus, smoking, obesity, dyslipidemia and inflammatory syndrome did not significantly influence the results of the EST. **Conclusions**: Typical angina, medical history of coronary artery disease, arterial hypertension, and reduced ejection fraction are strong predictors for a positive exercise stress test. **Keywords**: CARDIOVASCULAR RISK FACTORS, EXERCISE STRESS TESTING, PREDICTIVE VALUE.

Electrocardiogram exercise stress testing (EST) is an appropriate tool in diagnosis of coronary artery disease (CAD) (1). Even if the new European Society of Cardiology (ESC) guidelines recommend the use of stress imaging tests when available, EST still remains a useful option taking into account its widespread availability and easily interpretation (2). EST provides diagnostic and prognostic information like exercise capacity, chronotropic response to exercise, heart rate (HR) recovery, blood pressure (BP) response to exercise and for guiding cardiac rehabilitation (3). It offers quantitative and qualitative results, regarding chest pain (Kattus scale), perceived patient exertion (Borg scale), work-load (W and METs), maximum HR achieved and BP response, and electrocardiographic alterations. EST has an excellent safety profile, the risk being further reduced by a personalized careful medical history and clinical examination in order to define possible risks and contraindications (4). However, there are still de-

bates concerning categories of subjects that may benefit more from an EST and more studies emphasize on the limited clinical value of EST in asymptomatic adults (5).

CAD is related to the presence of risk factors. This led to developing total risk assessment charts, like the Framingham risk chart of total cardiovascular disease (CVD) and the SCORE risk chart of CVD death (6). Male sex and increasing age are unchangeable cardiovascular risk factors, very important determinants in clinical practice to stratify risk. Smoking affects 20% of the people worldwide and is responsible for one third of serious disease outcomes, mostly CVD, even in young adults and after an exposure of only a few years (7). Multiple studies showed that arterial hypertension causes endothelial injury which finally leads to cardiovascular events (8). Hypercholesterolemia is one of the most studied CV risk factors, predicting mortality, independently of age, both in subjects with and without preexistent CVD (9). Type 2 diabetes mellitus (DM) and metabolic syndrome are other conditions that favor the developing of coronary atherosclerosis (10). CAD is directly associated with obesity (body mass index > 30 kg/m²) but particularly with central obesity (waist circumference or waist-hip ratio) (11). Even if the cardio protective effects and health benefits of physical activity are irrefutable, increasing sedentary habits affect the quality of life and are correlated with a greater amount of chronic diseases, especially CVD (12). High resting heart rate has a worse prognostic in patients with or without CAD (13). Other cardiovascular risk factors, such as a positive family history, significant depression or reduced left ventricular ejection fraction influence the prognosis of CVD by accelerating the atherosclerotic processes, with worse outcomes in these patients (2).

However, very few studies appreciated comprehensively the influence of different traditional risk upon the EST. The aim of the study was to assess the impact of cardiovascular risk factors upon the positive EST results in patients referred for exercise testing.

MATERIAL AND METHODS

The current retrospective study included 294 patients, hospitalized over a two-year period (01.01.2011–31.12.2012) in the Cardiovascular Rehabilitation Clinic of the Rehabilitation Hospital at Iaşi, Romania, in whom an electrocardiogram EST was performed. We included patients with and without known CAD who were able to exercise and had no contraindications to performing the EST.

The patients were assessed according to: gender, age, rural or urban environment, obesity – body mass index (BMI) over 30 kg/m², smoking status, typical angina chest pain at admission, medical history of either angina or myocardial infarction, previous documented diagnostic or newly diagnosed arterial hypertension or type 2 DM. Dyslipidemia was defined, according to the ESC guidelines, as either total cholesterol over 190 mg/dl (4.9 mmol/L) or LDL-cholesterol over 115 mg/dl (3 mmol/L) or use of statin tratament for at least 6 months (6). According to the local laboratory, the inflammatory syndrome was present if the erythrocyte sedimentation rate was above 20 mm/1h or fibrinogen above 350 mg/dl or C-reactive protein (CRP) above 1 mg/dl. All patients performed a resting ecg and a transthoracic echocardiogram (Esaote MyLab50 ecocardiograph device) before the EST.

The EST was performed at the cycloergometer according to a standard protocol, starting with a power output of 25 W/min,

followed by an increment of 25 W every three minutes until endpoints were reached. We analyzed the maximal HR (according to the formula: 220 – patient' age) and BP, the Borg scale, work-load in Watts and METs, and the reasons for ending the EST. We considered a cut-off value for the submaximal exercise of 85% of age-predicted maximum HR. The EST was considered positive in the following situations: moderate to severe angina (≥ 3/4 on Kattus scale), severe exertional dyspnea, ST depression 80 ms after the J point more than 1 mm in three consecutive beats and in leads without diagnostic Q waves, pseudonormalization of T waves. The EST was terminated if systolic BP reached 240 mmHg or dropped more than 10 mmHg.

Statistical analysis was performed with SPSS 11.0 software. The mean values, standard deviations, frequencies were calculated. The significant differences were assessed by using the "t" Student test for two mean values and the "chi" square test for two frequencies, considering a "p" value < 0.05 statistically significant.

RESULTS

Mean age of patients was 55.75 ± 7.28 years (median 56 years); 51.7% were men. 294 ESTs were performed and 160 (54.42%) were positive, having at least one of the previous mentioned criteria for a positive EST.

In the positive EST (EST+) group, a submaximal HR was achieved in 59 patients (36.87%) while in the negative EST (EST-) group only 34 patients (25.37%) performed more than 85% of the maximal calculated HR (p=0.5). The two groups were matched for mean age, sex, and rural/urban origin (tab. I).

TABLE I

General data in the EST study groups

Parameter	EST+ Group	EST- Group
Age (years) (mean ± SD)	55.87 ± 6.50	55.61 ± 8.14
Male gender (no, %)	76 (47.5%)	76 (56.71%)
Urban origin (no, %)	76 (47.5%)	55 (41.04%)

As to the cardiovascular risk factors evaluated upon admission, we found statistically significant differences between the two groups. Typical angina chest pain was found in 88.12% of EST+ group compared with 76.11% in the EST- group (p=0.008). Personal medical history of angina or myocardial infarction was present in only 41.04% in the EST- group as to 61.87% in the EST+ group (p=0.0003). Arterial hypertension had a higher prevalence in the EST+ group (85.62% vs. 74.62%, p=0.01), as well as a lower ejection fraction in the EST+ group (61.18 ± 11.34 % vs. 63.34 ± 8.57 %, p=0.03). Resting ECG abnormalities (e.g. negative T waves, low ST segment depression, premature supraventricular or ventricular beats) were associated with a higher probability for a positive EST (49.37%) in the EST+ than in the EST- group (36.56%), p=0.02.

A positive EST was not significantly correlated with the presence of type 2 DM (p=0.12), with smoker status or with obesity (p=0.37). Patients with cardiovascular risk factors such as dyslipidemia or increased inflammatory markers were not prone for having a positive EST (tab. II).

TABLE II

Cardiovascular risk factors in the EST study groups

Parameter	EST+ Group	EST- Group	P
Typical angina chest pain at admission (%)	88.12	76.11	0.008
Medical history of angina or myocardial infarction (%)	61.87	41.04	0.0003
Rest ECG abnormalities (%)	49.37	36.56	0.026
Arterial hypertension (%)	85.62	74.62	0.019
Type 2 DM (%)	29.37	21.64	NS
BMI > 30 kg/m² (%)	50	44.77	NS
Current smokers (%)	47.5	47.01	NS
Dyslipidemia (%)	66.25	61.94	NS
Inflammatory syndrome (%)	16.87	17.16	NS
Ejection fraction (%)	61.18 ± 11.34	63.34 ± 8.57	0.035

The ECG stress test parameters were quite similar in the two groups. Maximum achieved HR was a bit lower in the EST- group (127.68 ± 19.51 / min) than in the EST+ group (129.85 ± 19.23 / min) but without statistical significance. Workload measured in METS showed no marked differences (5.65 ± 1.43 in EST+, 5.76 ± 1.60 in EST-) the same being true for the patient perceived exertion measured on Borg scale (14.27 ± 2.87 in EST+, 14.20 ± 2.67 in EST-).

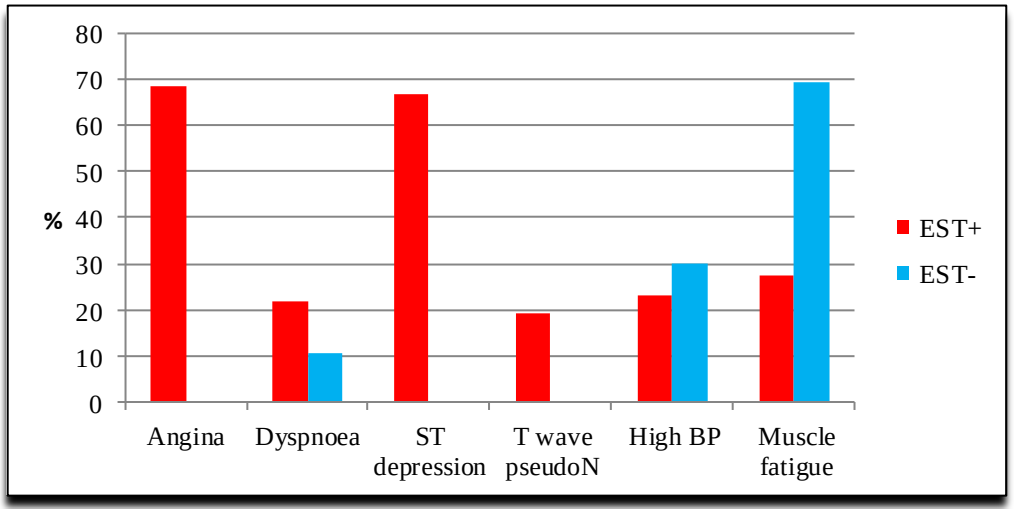

Fig. 1. Reasons for EST termination in the two groups

With regard to the reasons for terminating the EST, most patients in the EST- discontinued the test due to muscle fatigue (69.4%), severe arterial hypertensive re-

sponse (29.85%) or dyspnea (10.44%). In the EST+ group, most subjects presented moderate-severe angina (68.75%), ST segment depression more than 1 mm (66.87%), and less patients stopped because of muscle fatigue (27.5%) or high BP values (23.12%) (fig.1). Exercise-induced premature ventricular beats were present in about 30% of the patients in both groups.

DISCUSSION

According to the latest guidelines on the management of stable coronary artery disease, EST has a sensitivity of 45-50% and a specificity of 85-90% in detecting CAD, being especially indicated in patients with intermediate pre-test probability and left ventricular ejection fraction higher than 50% (2). However, if stress imaging testing is not available, ECG EST remains the first option in detecting CAD.

According to our study, 82.65% of the patients referred for an EST presented typical angina chest pain at admission, of which only 58% had a positive EST. This is in agreement with literature findings, EST being in about 50% non-conclusive with high false positive test results (14). The logical association between a positive EST and the presence of a medical history of angina or myocardial infarction is probably overrated in our study (64.28%), in comparison with 30-35% in other studies that made the same correlations (15). This is probably due to an overestimation of angina in patients presented with symptoms of chest pain.

Resting ECG abnormalities were seen in half of patients with positive EST, being a good marker for predicting a positive EST. In patients with known CAD, ST-segment abnormalities at rest are associated with a positive EST in more than 2/3 of cases (16).

Arterial hypertension is a strong predictor for CAD as well as for positive EST and is one of the major targets for treatment in both primary and secondary prevention (17).

As for type 2 DM and dyslipidemia, most patients having these risk factors associated a positive EST but without significant differences between groups. This may be due to the insufficient number of patients included in the study or to the high prevalence of these risk factors in patients with suspicious CAD (18).

Smoking and obesity also correlate with higher probabilities of CAD. In our study, they did not have a high predictive value for positive EST but it is well known that they are very important cardiovascular risk factors and could be integrated in risk scores in order to reach at least 80% negative predictive value for EST (19).

In our research, a high ejection fraction was associated with lower probability of positive EST. Our results are similar with other studies which state that patients with normal ejection fraction, without diabetes and good exercise capacity are unlikely to have a positive test result (20).

CONCLUSIONS

According to our research, typical angina chest pain, medical history of angina or myocardial infarction, resting ECG abnormalities, arterial hypertension and a lower ejection fraction are strong predictors for a positive EST.

Other important cardiovascular risk factors, such as type 2 DM, smoking, BMI over 30 kg/m², dyslipidemia or increased inflammatory markers, were not correlated with a positive EST and have a less predictive value.

BACTERIAL MENINGITIS DURING SEPSIS IN DIABETIC PATIENT (Abstract): **The aim** of the study was to evaluate the etiology, clinical features and outcome in diabetic patients with bacterial meningitis, as a nervous system determination during invasive infections. **Material and methods:** In a retrospective study, conducted over a period of three years, we have analyzed clinical and etiological aspects of 445 patients over 18 years old, diagnosed with sepsis of known (positive cultures from normally sterile sites) or suspected etiology (positive cultures from pus), 95 of them being included in the diabetic group. **Results:** Bacterial meningitis was diagnosed in 16 of 95 diabetic patients (16.8%) and 43 of 350 (12.3%) non-diabetic patients (χ^2=0.98; GL=1; p=0.322). Among the multiple co morbidities associated in diabetic patients, as suggested by a higher Charlson score (5.44 *vs.* 3.25) (p=0.001), the most common underlying condition was chronic liver disease (31.3% *vs.* 25.6%) (p=0.916). The isolation of the microorganism concurrently from cerebro-spinal fluid and other sites (blood cultures and pus) was more frequently encountered in diabetics. The clinical picture was dominated by altered consciousness (68.8% *vs*. 23.3%) (p=0.003), while fever was less present (37.5% *vs*. 88.4%) (p=0.0003). The most frequently involved microorganism in the etiology of meningitis was *S. aureus* (31.3 *vs*. 23.3%) (p=0.771) and Gram negative bacilli: *E. coli* (12.5% *vs.* 4.7%) (p=0.629) and *Klebsiella* spp. (12.5% *vs.* 9.3%) (p=0.902). **Conclusions**: Altered consciousness was more frequent in diabetic patients group (68.8% *vs.* 23.3%) (p=0.003) where the absence of fever at admission was a more common finding than in non-diabetic septic patients with meningitis (37.5% *vs.* 88.4%) (p=0.0003).
Keywords: BACTERIAL MENINGITIS, SEPSIS, DIABETES

Bacterial infections of the central nervous system during invasive bacterial disease in diabetic population represents a challenge for the diagnosis, mainly because the clinical signs are often masked by acute and chronic complications of the diabetes, which may delay early recognition and adequate treatment. The epidemiology of bacterial meningitis varies in different populations. Several factors such as age, geographic distribution, underlying medical and surgical conditions, way of acquisition and the vaccination status may influence the prevalence of the involved pathogens (1). Association with diabetes mellitus as a co morbidity was found to be around 4-5% in patients with adult community-acquired bacterial meningitis in western reports, and as high as 25% in patients with bacterial meningitis from Taiwan (2). Therefore, the aim of the study was to evaluate the etiology, clinical features and outcome in diabet-

ic patients with bacterial meningitis, as a nervous system determination during invasive infections.

MATERIAL AND METHODS

In a retrospective study, conducted over a period of three years (2008-2010), we have analyzed the clinical and etiological aspects of 445 patients over 18 years old with sepsis admitted to the Clinical Hospital of Infectious Diseases Iaşi. Only cases of sepsis with known etiology were included in the study, documented by positive cultures from different normally sterile sites or suspected etiology (positive cultures from pus). According to American Diabetes Associations criteria, 95 of patients were included in the diabetic group. Patients with bacterial meningitis were identified based on the microbiological records of the cerebrospinal fluid (CSF): direct examination, positive cultures and latex agglutination assay.

The associated Chronic co morbid medical conditions were assessed by Charlson co morbidity score (3). Other variables such as onset-admission period longer than 48 hours, length of stay, discharged status, adequate treatment, mortality were collected. All the information represented data available from medical charts during hospitalization and long term outcome information was not available. For statistical analysis, all information was centralized in an *Excel* data base and differences between patient groups (diabetics and non-diabetics) were assessed using *SPSS* application, version 17.0. A p-value of < 0.05 was considered to be statistically significant.

RESULTS AND DISCUSSION

During the period of study of three years, among 445 patients diagnosed with sepsis of known or suspected etiology, bacterial meningitis was documented in 95 cases, 16 (27.1%) of them being patients with diabetes mellitus. Regarding the frequency of meningitis diagnosed during invasive disease, no statistically significant difference was noted between the studied groups: 16 of 95 diabetic patients (16.8%) and 43 of 350 (12.3%) non-diabetic patients (χ^2=*0.*98; GL=1; p=*0.*322) (fig.1).

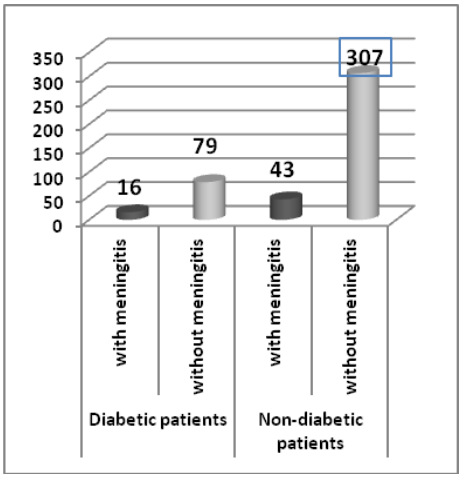

Fig. 1. The structure of the studied groups with bacterial meningitis

The majority of cases in both groups were males (68.8% respectively 74.4%). The median age of the patients with diabetes was significantly higher (63.88 *vs.* 52.07 years) (p=*0.*050).

Among the multiple co morbidities associated in diabetic patients, as suggested by a higher Charlson score (5.44 *vs.* 3.25) (p=0.001), chronic liver disease was the most commonly noted (31.3% *vs.* 25.6%) (p=0.916). Other underlying conditions and predisposing factors are shown in table I. Clinical evaluation in the first 24 hours of hospitalization, appreciated with SAPS II (Simplified Acute Physiology Score), revealed more severe forms of sepsis in diabetic patients (54 *vs.* 26.62) (p<0.001) (tab. I).

TABLE I

Characteristics of diabetic and non-diabetic patients with bacterial meningitis

Characteristic	Diabetic patients (n=95) (%)	Non-diabetic patients (n=350) (%)	p
Patients with bacterial meningitis (no/% of the whole group)	**16 (16.8%)**	**43 (12.3%)**	*0.*322
Median age (years)	**63.88±6.91**	**52.07±15.46**	***0.*050**
Gender			
Male	11 (68.8%)	32 (74.4%)	*0.*916
Female	5 (31.2%)	11 (25.6%)	
Predisposing conditions			
Chronic liver disease	5 (31.2%)	11 (25.6%)	0.916
Alcoholism	2 (12.5%)	6 (13.9%)	0.777
Chronic kidney disease	1 (6.3%)	1 (2.3%)	0.945
Tumors	1 (6.3%)	2 (4.7%)	0.676
AIDS	-	2 (4.7%)	0.945
Charlson Score	5.44±1.75	3.25±1.83	**0.001**
SAPS II	54.0±7.27	26.62±10.13	**0.001**

Transfer	4 (25%)	4 (9.3%)	0.255

[a]MODS – multiple organ dysfunction syndrome, [#]CSF – cerebrospinal fluid

A period of more than 48 hours between the onset of clinical signs and admission in hospital was noticed in diabetic patients (37.5% *vs.* 23.3%) (p=0.444). This is probably due to the fact that classical clinical signs of meningitis were less obvious, metabolic imbalance being also a cause of altered consciousness, which may be misleading, delaying thus the diagnosis of meningitis.

Before admission, the clinical picture was dominated by altered consciousness (68.8% *vs.* 23.3%) (p=0.003), while fever was less present (37.5% *vs.* 88.4%) (p=0.0003). Seizures were more often encountered in non-diabetic patients 16.3% *vs.* 12.5%, but without statistical significance (p=0.961).

Patients with diabetes were more likely to have other foci of infection than patients without diabetes, multiple organ dysfunction syndrome being documented in 25% of this immunocompromised group *vs.* 11.6% in the non-diabetic group (p=0.388). It is noteworthy that the isolation of the same microorganism concurrently from cerebrospinal fluid and other different pathologic collections (blood cultures and pus) was also more frequently encountered in diabetic group (81.3% *vs.* 32.6%) (p=0.0003). Complications of bacterial meningitis were epiduritis (one case in each group) and brain abscess (one case in the non-diabetic group).

TABLE II

The etiology of bacterial meningitis in diabetic and non-diabetic patients

Etiology	Diabetic patients (n=16)	Non-diabetic patients (n=43)	P
S. aureus	5 (31.3%)	10 (23.3%)	0.771
Coagulase-negative staphylococci	2 (12.5%)	3 (7.0%)	0.880
Streptococcus grup B	1 (6.3%)	-	0.604
Streptococcus pneumoniae	2 (12.5%)	12 (27.9%)	0.372
E. coli	2 (12.5%)	2 (4.7%)	0.629
Klebsiella spp.	2 (12.5%)	4 (9.3%)	0.902
Neisseria spp	1 (6.3%)	2 (4.7%)	0.676
Aerococcus viridans	1 (6.3%)	1 (2.3%)	0.945
Enterococcus spp	-	3 (7.0%)	0.676
Acinetobacter spp	-	3 (7.0%)	0.676
Pseudomonas aeruginosa	-	2 (4.7%)	0.945
Citrobacter freundii	-	1 (2.3%)	0.604

The mean hospital period of stay varied between 12 and 16 days in both groups (p>0.05).

Unfavorable outcome was not signifi-

cantly different in diabetic and non-diabetic patients.

Transfer to other medical or surgical clinics was necessary in 25% of diabetic cases (neurosurgery - 1 case of epiduritis, and in intensive care service - 3 cases, for acute respiratory distress syndrome).

S. aureus was the most common pathogen responsible for meningitis in diabetic patients with sepsis (31.3 *vs.* 23.3%) (p=0.771) followed by Gram negative bacilli: *E. coli* (12.5% *vs.* 4.7%) (p=0.629) and *Klebsiella* spp. (12.5% *vs.* 9.3%) (p=0.902). We did not find significant differences between the two groups of patients regarding the etiology (tab. II).

DISCUSSION

A report from Koreea (4) analyzing cases of community-acquired meningitis from 1998 to 2008 showed that 31.3% of patients were diabetic compared with 27.1% in our cohort of patients with meningitis during sepsis. It is worth noting that we included in our study only cases with known etiology (positive cultures of CSF or blood), therefore, true prevalence of bacterial meningitis may be underestimated. In a previous Romanian study, conducted on 844 cases of meningitis, diabetes was associated in only 1.5% of cases. These important differences may be due to the fact that in the study patients younger than 18 years were also included, children under 15 years representing 43.5% and only 7.7% being patients over 65 years (5).

Similar studies from Taiwan showed a high incidence of diabetes (34-36%), among the adult patients with community-acquired spontaneous bacterial meningitis (1, 6). In a prospective study from the Netherlands on adult community-acquired bacterial meningitis, diabetes was reported in 7% of cases (7).

A lot of reports support the concept that changes in mental status are the strongest clinical indicators of bacterial meningitis in elderly, the same findings being noted in our study in diabetic patients, whose median of age was higher than in non-diabetics (8. 9). In this category of patients, altered consciousness was noted in almost 70% of cases.

Beside diabetes, alcohol consumption and/or liver cirrhosis were frequent additional underlying conditions in our study, being present in more than 80%.

The etiology was related to the most prevalent pathogen causing nosocomial infections (*Staphylococcus aureus*/ coagulase negative staphyloccocci) in diabetics group, whereas in non-diabetic patients, *S. pneumonia* was more frequently isolated. In community-acquired meningitis in the same region, staphylococcus accounted for only 5% of cases with known etiology (5).

This figure is in contrast with the findings of the Taiwanese report that mentioned *Klebsiella* species as the most frequent etiological agent of meningitis in diabetic patients (2).

An investigation concerning community-acquired meningitis in the Hospital of Infectious Diseases Iaşi during 1998-2007 reported that the overall mortality rate was 13.1%, lower than that found in the Korean study (19%) (4, 5).

Kragsbjerg et al. in Sweden, revealed a mortality rate of 16% in patients over 14 years of age with pneumococcal meningitis, while, the mortality rate was 33% for those over 70 years of age (10). This value contrasts with the mortality rate of 30% reported for patients with pneumococcal meningitis in USA (11).

The rate of death in our study was not

statistically different among patients with and without diabetes (12% *vs.* 25%).

There are some controversies among the studies concerning the analysis of variables associated with prognosis. In van de Beek study, the strongest risk factors for an unfavorable outcome are those that are indicative of systemic compromise, a low level of consciousness and *S. pneumoniae* etiology (11). Factors associated with poor prognosis in a previous local analysis were: pneumococcal etiology, age over 60 and the presence of seizures or coma at admission (5).

Other risk factors associated with fatality rate were the absence of headache (finding probably associated with the delay in diagnosis), immunocompromised status, presence of coma and pneumonia – in the study of Papaiordanou (12).

A high index of suspicion for meningitis must be maintained during the healthcare of diabetic patients with changes in mental status and/or fever, because a delay in diagnosis and therapy will result in a devastating illness.

Accurate knowledge of epidemiology of sepsis and meningitis in diabetic patients and local pattern of antibiotic susceptibility may help us in filling the gaps related to the outcome of this particular category of patients.

CONCLUSIONS

This study shows a relatively high frequency of meningitis during sepsis in diabetic patients.

Bacterial meningitis was more frequently microbiologically documented (*S. aureus*, *Coagulase-negative staphylococci*, *Streptococcus pneumoniae*, *E. coli*, *Klebsiella spp*.) from the CSF in diabetic population.

The risk of late recognition was higher, mainly due to chronic complications of diabetes. Altered consciousness was more frequently in diabetic patients (68.8%) in whom the absence of fever at admission was a more common finding (88.4%) than in non-diabetic septic patients with meningitis.

NEWS

METASTATIC CROHN DISEASE - A RARE CUTANEOUS ENTITY

Metastatic Crohn disease is a rare cutaneous disorder characterized by noncaseating, granulomatous skin lesions present at sites anatomically separate from the gastrointestinal tract.First described by Crohn et al, Crohn disease is a chronic granulomatous inflammatory bowel disorder that may involve any segment of the gastrointestinal tract. Along with the characteristic gastrointestinal findings of this disease, patients with Crohn disease may also present with extraintestinal manifestations including ocular findings, musculoskeletal pathology, and mucocutaneous manifestations. Mucocutaneous findings are the most frequent extraintestinal manifestation of Crohn disease; 22% to 44% of patients present with mucocutaneous changes, which may be categorized as granulomatous skin disease. Included within the granulomatous cutaneous category are perianal, peristomal, and perifistular inflammatory lesions, which are contiguous with the gastrointestinal tract and are the most common cutaneous manifestations of Crohn disease. Parks et al were the first to describe the presence of sterile, noncaseating, granulomatous lesions of the skin at sites noncontiguous with the gastrointestinal tract in patients with Crohn disease. This entity is known as metastatic Crohn disease (MCD), the name first coined in 1970 by Mountain. It is characterized by cutaneous, noncaseating granulomas at sites anatomically separate from the gastrointestinal tract. It is the least common dermatologic manifestation of Crohn disease, and the differential diagnosis includes numerous similarly appearing, granulomatous skin entities. Males and females appear to be equally affected, and children tend to present with clinical lesions different from those of adults. An integration of clinical information, microscopic findings, and ancillary studies is necessary to accurately diagnose this rare cutaneous disease. Our objective is to review the clinical features, histopathologic characteristics, suggested pathogenesis, differential diagnosis, and current therapeutic options of metastatic Crohn disease. PLATELET INDICES IN PATIENTS WITH DE NOVO PORTAL VEIN THROMBOSIS AND LIVER CIRRHOSIS

Irina Gîrleanu[1], Anca Trifan[2], Camelia Cojocariu[2], Mihaela Dimache[2], Ana-Maria Sîngeap[2], Oana Stoica[2], C. Sfarti[2], C. Stanciu[2]

PLATELET INDICES IN PATIENTS WITH DE NOVO PORTAL VEIN THROMBOSIS AND LIVER CIRRHOSIS (Abstract) Platelet indices are markers of platelet reactivity used for thrombotic risk assessment in patients with cardiovascular diseases, and recently in venous thrombosis. **Aim:** To assess the diagnostic value of platelet indices in patients with non-malignant de novo portal vein thrombosis and liver cirrhosis. **Material and methods**: We conducted a prospective, case-control study on patients admitted to a tertiary center in the interval January, 2010 – December, 2012. Included in the study were 54 patients with portal vein thrombosis (PVT) and 54 controls. Patients with known malignancy, sepsis, thrombophilia, on anticoagulant or antiaggregant therapy, acute or chronic inflammatory diseases, severe anemia, renal failure, acute coronary syndrome, and chronic pulmonary disease were excluded from the study. **Results**: Both groups were comparable for baseline characteristics. Mean platelet volume, platelet distribution width (PDW) and plateletcrit were higher in the PVT group. In a multivariate logistic regression analysis, significant predictors of the presence of PVT were mean platelet volume (MPV), PDW, and procalcitonin (PCT). **Conclusion**: Our data suggest that increased platelet indices contribute to the prethrombotic state in liver cirrhosis and that larger platelets may play a specific role in thrombosis despite thrombocytopenia. **Keywords:** PORTAL VEIN THROMBOSIS, PLATELET INDICES, LIVER CIRRHOSIS, THROMBOCYTES.

Portal vein thrombosis (PVT) is an important cause of morbidity and mortality in patients with liver cirrhosis (LC) (1). The incidence ranges between 5% and 26%, and is higher in patients on transplant waiting list (2,3). Predisposing clinical conditions for PVT are advanced LC, low portal vein velocity, malignancy, and a wide variety of acquired and inherited hematological diseases (4). Despite thrombocytopenia, platelets are important in LC, playing a major role in hemostasis and other important functions such as inflammation, host defense and anfiogenesis and fibrosis (5,6). The routine platelet function tests including bleeding time and aggregometry have a low positive predicting value in differentiating between bleeding and thrombotic risk in LC, and new methods for assessing platelet function are needed (6).

Platelets are heterogeneous in size, density, and reactivity (6). Mean platelet volume (MPV) shows platelet size and may reflect platelet function and activity (7).

Since larger platelets are more reactive than the normal size ones, elevated MPV values were demonstrated to be a risk factor for arterial thrombosis and cardiovascular diseases (8,9). However, new data sustain that MPV and other parameters including platelet distribution width (PDW) and plateletcrit (PCT) may be used as indicators of platelet function and activation in patients with vein thrombosis (10). PDW directly measures the variability in platelet size and is a marker of platelet activation (11). A high PDW value could suggest a greater production of larger reticulated platelets. Of all platelet indices, PCT provides more comprehensive data about total platelet mass because it is equivalent to MPV and platelet count (PLT), where $PCT=PLTxMPV/10^7$ (11).

Recently it has been demonstrated that MPV is elevated in patients with deep vein thrombosis and significantly higher in patients with non-cirrhotic PVT. Therefore, in the present study we aimed at investigating whether platelet indices (MPV, PDW, and PCT) could have a diagnostic value for PVT in cirrhotic patients, despite thrombocytopenia.

MATERIAL AND METHODS

Study population

We conducted a prospective, case-control study on patients with liver cirrhosis admitted to a tertiary hospital in the interval January, 2010- December, 2012 in which a diagnosis of PVT was made during the study interval. Excluded from the study were the patients previously diagnosed with hereditary thrombophilia, hepatocellular carcinoma or other known malignancies, patients on anticoagulant or antiaggregant therapy, and patients with acute or chronic inflammatory diseases, severe anemia, renal failure, acute coronary syndrome, and chronic pulmonary disease. Between January, 2012- December 2012, 3124 cirrhotic patients were admitted to our department, of which a control group was randomly selected. After a detailed history and physical examination, all patients were subjected to hematological and biochemical blood tests and abdominal ultrasound. The study was performed in accordance with the Declaration of Helsinki and our local ethical committee approved the study. A written consent was obtained from all patients.

Portal vein thrombosis diagnosis

Portal vein thrombosis was diagnosed by abdominal ultrasound and Doppler ultrasound after 8 hours fasting. A Philips HD11XE ultrasound machine equipped with a 3.5 MHz convex transducer was used. PVT was confirmed by computed tomography with IV contrast. PVT was classified into 2 categories: complete and partial.

Laboratory data

Fasting peripheral blood sample was drawn from the antecubital vein using a 21-guage needle with a vacutainer and minimal stasis. The blood sample was collected into tubes containing 2.7 mL EDTA for platelet count, MPV, PDW, and PCT analyses. Platelet indices were measured using an automated system (Sysmex XS-1000i), by flow cytometry (11). The measurements were performed within 30 minutes after vein puncture to rule out the possible swelling of platelets. The reference ranges in our hematology laboratory are: MPV: 8.5 to 12.0 fL, PDW: 10.0 to 18.0 %, and PCT: 0.12 to 0.40 %.

Statistical analysis

Data were analyzed using SPSS Software Version 17.0 for Windows (SPSS Inc.,

Chicago, Illinois). Continuous variables were presented as mean ± standard error and categorical variables as frequency and percentage. Student's t test was used to compare normally distributed continuous variables, and the Mann-Whitney U test for variables without normal distribution. The χ^2 test or the Fisher exact test was used to compare categorical variables. Pearson analysis was used to analyze the correlations between platelet indices. Separate logistic regression analyses were used to identify univariate predictors of PVT, and a subsequent stepwise (forward conditional) regression analysis was performed (parameters with a *p* value of <0.1 in univariate analysis were included in the model). Receiver–operating characteristic (ROC) analyses were used to determine the cutoff values and the sensitivity/ specificity of platelet indices. The odds ratios (OR) and the 95% confidence intervals (CI) were calculated. A 2-tailed *p* value of <0.05 was considered statistically significant.

RESULTS

There were no significant differences between the two groups in age, sex, clinical risk factors (hypertension, diabetes, smoking), and laboratory parameters (cholesterol, fasting plasma glucose, white blood cell count, hemoglobin, platelet count, etiology of LC, MELD score and Child-Pugh class) (tab. I).

TABLE I

Baseline demographic, clinical and laboratory characteristics of the study population

Characteristics	PVT group (n=54)	Control Group (n=54)	p value
Age, y	61.5±11.0	62.3±12.3	0.471
Male,%	34(62.9%)	33(61.1%)	0.755
Diabetes,%	7(12.9%)	8(18.4%)	0.438
Smoking,%	22(40.7%)	18(33.3%)	0.122
Etiology (alcoholic/virus B/C/other)	23/4/25/2	23/6/22/3	0.246
MELD score	12.6±5.5	11.9±7.5	0.685
Score Child	7.6±2.3	7.8±2.1	0.724
Child-Pugh class (A/B/C)	20/10/24	18/14/22	0.111
Blood glucose (mg/dl)	128.9±60.1	137±83.7	0.366
WBC count, per ml	9860±3240	8844±3498	0.229
Hemoglobin, g/dl	12.2±2.07	11.4±2.5	0.584
AP	75.2±19.6	73.7±20.6	0.256
Platelet count,x10^9 per L	176±11.2	141±14.3	0.239

Abbreviations: PVT, portal vein thrombosis, WBC, with blood cell, AP prothrombin activity.

According to the time scale of PVT, 25 (46.2%) patients had acute and 29 (53.8%) chronic PVT. In all, PTV was complete in 15 (27.7%) cases and partial in 39 (72.3%).

MPV was significantly higher in the PVT group compared with the controls (811.2 + 1.0 fL *vs* 9.7+1.2 fL [95% CI

0.07-0.99], p=0.05). PDW was also significantly higher in the PVT group compared with the control group (14.3 + 3.13 % *vs* 12.2 + 2.38 % [95% CI 0.10-2.48], p=0.048, respectively). PCT was, however, significantly lower in PVT group compared with the controls (0.19+0.12% *vs* 0.14+0.06% [95% CI 0.08-0.09], p=0.015, respectively). In addition, there was a significant inverse relationship (fig. 1).

In a multivariate logistic regression analysis, significant predictors of the presence of PVT were MPV, PDW, and PCT (tab. II). For MPV, the multiple-adjusted OR of the presence of PVT was 2.3 (95% CI, 1.77-2.37); for PDW, the multiple-adjusted OR of the presence of PVT was 2.4 (95% CI, 1.435-3.85); and for PCT, the multiple-adjusted OR of the presence of PVT was 1.79 (95% CI, 0.95-2.86).

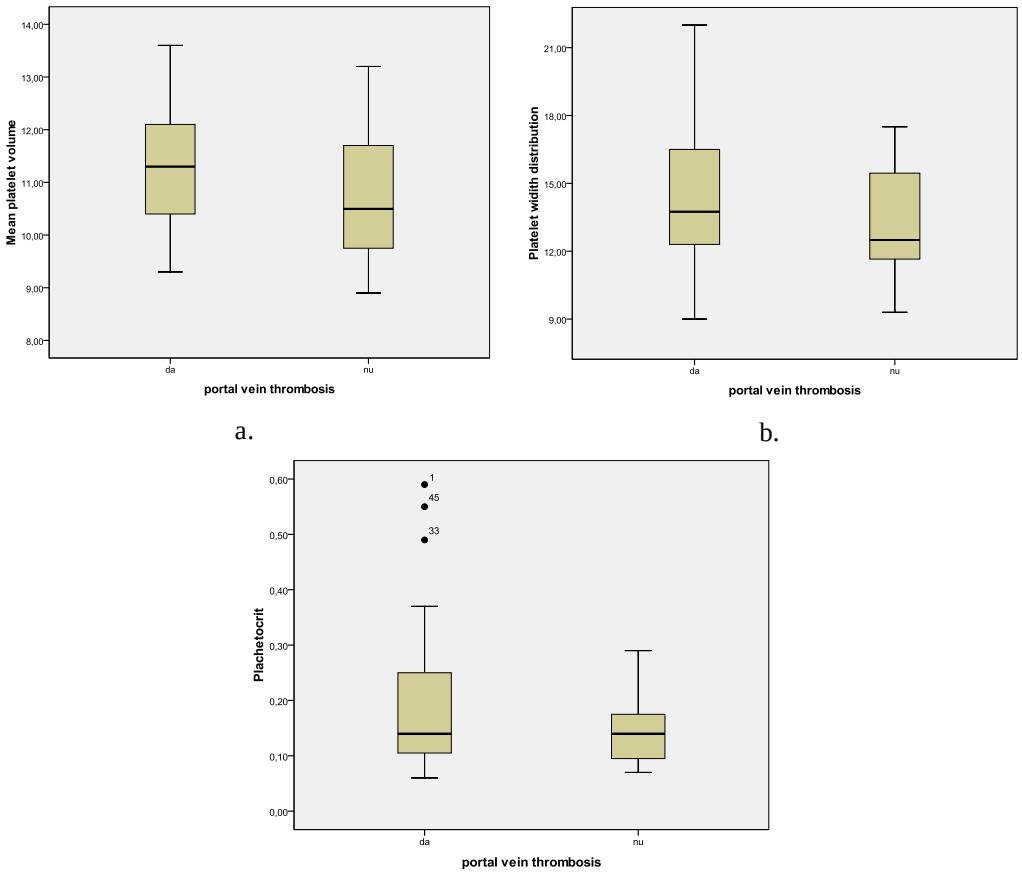

Fig. 1. Platelet indices in patients with liver cirrhosis with and without PVT: a-MPV, b- PDW, c- plachetocrit**.**

The cutoff values of 11.0 fL, 11.7%, and 0.11% for MPV, PDW, and PCT, respectively, were found to be moderately sensitive and specific for predicting PVT.

TABLE II
Multivariate regression analysis of the presence of PVT

Variable	β	±SE	p Value
MPV	-0.053	0.740	0.046
PDW	0.011	0.258	0.012
PCT	-7.584	5.972	0.026

Finally, to determine the best cutoff values of platelet indices for predicting PVT, ROC analyses were performed. The areas under the ROC curves for these indices used to detect PVT were calculated (tab. III) and the sensitivity and specificity of the best cutoff values were determined (tab. IV).

TABLE III
Receiver operating characteristic analysis for platelet indices to predict PVT

Variable	Area under the ROC curve	95% CI	p Value
MPV	0.610	0.46-0.75	0.022
PDW	0.579	0.43-0.71	0.035
PCT	0.576	0.44-0.71	0.038

The cutoff values of 11.0 fL, 11.7%, and 0.11% for MPV, PDW, and PCT, respectively, were found to be moderately sensitive and specific for predicting PVT.

TABLE IV
Sensitivity and specificity of the cutoff values of platelet indices

Variables	Cutoff value	Sensitivity (%)	Specificity (%)
MPV	11.0	53%	37%
PDW	11.2%	72%	63%
PCT	0.1%	69%	55%

DISCUSSION

In the present study, we have found that the platelet activity indices were significantly and independently associated with the presence of PVT. Platelet activity can be influenced by a multitude of variables (12), therefore it is difficult to predict the extent of platelet reactivity in an individual. A practical, reliable, and available index of platelet activation has not been discovered although considerable amount of research has been performed (11).

Various laboratory methods including platelet count and size, aggregates, and released substances from activated platelets have been introduced for the detection of platelet activity (11). However, they have different advantages and disadvantages. MPV is an inexpensive and easily available biomarker. It is routinely available in inpatient and outpatient setting at a relatively low-cost. Increased MPV values are related to various cardiovascular risk factors, disorders and inflammatory processes resulted in arterial and venous thromboses (9,10). Circulating platelets are heterogeneous in size, metabolism, functional activity, and density. Larger platelets are metabolically and enzymatically more active than smaller platelets, containing more prothrombotic material, with increased thromboxane A2 and B2 per unit volume and glycoprotein IIb-IIIa receptor expression (13). In healthy participants, there is a nonlinear inverse

correlation between MPV and platelet concentration: MPV tends to decrease in participants with higher platelet counts, as found in our study (14,15).

In previous studies, increased MPV was found to be associated with non-alcoholic fatty liver disease, hepatits C and B and advanced fibrosis (16). Recently, Braekkan et al. reported that MPV is a risk factor in venous thromboembolism (10). Our findings provide further evidence that platelet activation, measured by elevated MVP, PDW and PCT may contribute to the pathogenesis of venous thrombosis.

To our knowledge, this study has examined for the first time the relationship between all platelet indices, PVT and liver cirrhosis. Pizzuli et al. suggested that because platelets stay in the circulation 7-11 days, they might be detected days before symptoms appear (17). We believe that the same correlation might exist between platelet indices and PVT. At routine checkup a cirrhotic patient with elevated MPV, PCT and PDW might be a suspect for PVT, despite thrombocytopenia. However, to demonstrate the possible predictive value of platelet indices for PVT more prospective studies on larger patient groups should be performed.

Our data suggested that increased platelet indices contribute to the prethrombotic state in liver cirrhosis and that larger platelets may play a specific role in thrombosis despite thrombocytopenia.

Platelet indices could provide useful clinical information and be built into a risk assessment algorithm for PVT. This study supports the fact that platelet reactivity is important in the pathogenesis of PVT.

An important limitation concerning the predictive value of MPV, MPM, and MPC is the absence of well-defined limits to differentiate between activated and nonactivated platelets. Other platelet activity indices, such as radio-labeling methods, aggregometry procedures, platelet-specific eicosanoids, other release reactions such as serotonin and histamine, adhesion molecules, flow cytometric investigations, platelet function analyzers, thromboelastography, and plasma factors influencing platelet activation such as fibrinogen were not used in our study.

CONCLUSIONS

Patients with PVT and liver cirrhosis had abnormalities of platelet activation compared with the group without PVT, and these platelet abnormalities may partly contribute to the pathophysiology of PVT. Platelet activity indices including MPV, PDW, and PCT may be used in predicting PVT in patients with liver cirrhosis. However, these results have to be confirmed in larger, prospective, and more homogenous study groups.

LASER TREATMENT OF ONYCHOMYCOSIS

The efficacy of in vitro laser irradiation against fungi, for treatment of onychomycosis, was investigated by Paasch *et al*. For this puspose, 808, 980 and 1064-nm lasers were used to heat cell culture media and nail clippings and several *Trichophyton, Microsporum* and *Candida* species were subjected to laser irradiation, followed by incubation for 6 days. The results showed a thermal effect for 980-nm and 1064-nm laser systems on cell culture media and nail clippings. Growth inhibition was detected for *Candida guilliermondii* and *Trichophyton interdigitale* and complete growth impairment was achieved at temperatures above 50°C. For other pathogens, only reduced growth was observed. (Paasch U, Mock A, Grunewald S, Bodendorf MO, Kendler M, Seitz AT, et al. Antifungal efficacy of lasers against dermatophytes and yeasts in vitro. (*Int J Hyperthermia.* 2013 Sep;29(6):544-50. doi: 10.3109/02656736.2013.823672)

BODY COMPOSITION ALTERATIONS IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE (Abstract): Metabolic disorders are involved in the pathogenesis of some comorbid conditions such as atherosclerosis and cardiovascular diseases, which frequently occur in COPD patient. These disorders may also associate alterations in body composition. **Aim:** To determine the particularities of body composition, assessing its relationship with respiratory function and clinical status in COPD patients. **Material and methods:** A prospective case-control study including 31 patients with COPD admitted to the Clinic of Pulmonary Diseases Iasi from April 2011 to September 2012, and 29 subjects without lung diseases which served as controls. Body composition (body fat, lean body mass, body water) and basal metabolic rate were measured using bioelectrical impedance analysis. Other assessments included anthropometric parameters, spirometry, 6-minute walk test. In COPD patients, dyspnea scale and health impairment assessment by St George's Respiratory Questionnaire (SGRQ) were used. **Results:** In COPD group, 67% of the patients were normal weight, 10% underweight, 10% overweight and 13% obese. The results showed that lean body mass ($p<0.001$), dry lean mass ($p<0.001$), total body water ($p<0.001$) and basal metabolic rate ($p<0.001$) were lower in the COPD patients as compared to the controls. These findings significantly correlate with age, dyspnea, severity of airway obstruction and exercise capacity in patients with COPD. No significant differences between study groups were observed in body fat mass. **Conclusions:** Lean body mass, dry lean mass, and total body water are altered in COPD patients and significantly correlate with age, clinical and functional severity of COPD. **Keywords:** COPD, BODY COMPOSITION, FAT MASS, LEAN MASS.

Chronic obstructive pulmonary disease (COPD) is associated with an increasing prevalence and a high mortality in the coming decades, being a challenge for the clinicians and a leading public health problem worldwide (1). One of its specific features associated with increased morbidity and mortality is the presence of chronic comorbidities. The complex pathogenic link between COPD and comorbidities seems to involve systemic inflammation which represents another important feature of COPD (2).

The metabolic syndrome is frequently diagnosed in overweight COPD patients, its association with increased systemic inflammation independent of lung function impair-

ment being thus proved (3). However, data on metabolic alteration in COPD are still poor and inconsistent. The "obesity paradox", defined as an inverse association of good health, survival and obesity in COPD patients was described. A higher mortality was found among underweight COPD patients, whereas overweight patients had a lower overall mortality (4). Other researches have found a low fat-free mass frequently associated in COPD patients, even when body mass index (BMI) was normal. Furthermore, low fat-free mass is considered an independent predictor of mortality in COPD (5).

Plasma adiponectin, an adipose tissue-derived specific protein with anti-inflammatory and anti-atherosclerotic effects, correlates with body weight loss and systemic inflammation in COPD, some researches concluding that adiponectin may reduce cardiovascular events in underweight patients (6).

However, cardiovascular diseases, many of these involving atherosclerosis and metabolic disorders, represent an important comorbidity accounting for 26% of the cause-specific mortality in COPD patients (7).

COPD patients have excessive visceral fat even in advanced stages of the disease despite the absence of obesity (8). Physical inactivity, a commonly observed feature in COPD, might be a determinant of visceral fat accumulation (9).

Given the pathogenic and prognostic implications of fat mass alteration, our study aimed to determine the particularities of body composition, including fat body mass, lean body mass, body water and basal metabolism, in view of assessing their relationship with respiratory function and clinical status in COPD patients.

MATERIAL AND METHODS

We conducted a prospective case-control study in which we determined and compared body composition in patients with COPD and subjects without lung disease. The study included patients admitted to the Clinic of Pulmonary Diseases Iasi in the interval April 2011 - September 2012, diagnosed with COPD according to the criteria of Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines: chronic dyspnea, cough, or sputum production, and persistent airflow limitation, confirmed by spirometry (a ratio of forced expiratory volume in 1 second (FEV1) to forced vital capacity (FVC) of <0.7 after bronchodilator administration) (1).

The control group included subjects with no history of lung diseases, clinical symptoms suggestive of COPD or respiratory dysfunction, based on the results of pulmonary function tests. COPD patients and controls were matched for sex and age. Male gender and age between 45 and 85 years were inclusion criteria for both COPD patients and controls. Cachexia was the exclusion criterion for the control group.

The study was approved by the Ethics Committee of the Clinic of Pulmonary Diseases Iasi and the patients were enrolled only after they provided appropriate informed consent.

The study protocol included the clinical and anthropometric assessment of the subjects: body height and weight were measured and BMI was calculated as weight/height^2 (kg/m^2). We used the World Health Organization classification of BMI which categorizes BMI into the following categories: underweight (BMI≤18.5 kg/m^2), normal weight (BMI: 18.5-24.99 kg/m^2), overweight (BMI: 25-29.9 kg/m^2), and obesity (BMI>30 kg/m^2) (10). Smoking history was expressed as the number of pack-years (py). For the COPD group the

degree of dyspnea was estimated using the Modified Medical Respiratory Council (MMRC) dyspnea scale (11).

Pulmonary function was assessed by spirometry, including postbronchodilator FEV1 measuring, to confirm the diagnosis of COPD in the corresponding group. FEV1 was expressed as percentage of predicted value. Exercise capacity was assessed in all subjects by the 6-minute walk test (6MWT). This was performed according to the standards of the American Thoracic Society (12). Health impairment in COPD patients was measured by St George's Respiratory Questionnaire (SGRQ). This provides three component scores: symptoms, activity, and impacts, in addition to SGRQ total score (13). Body composition was measured using bioelectrical impedance analysis with BodyStat 1500 analyzer (Bodystat Ltd, Douglas, Isle of Man). The device measures/estimates the following parameters: body fat percentage and fat weight (kilograms), lean mass percentage and lean mass (kilograms), body water percentage and total body water (liters), basal metabolic rate (kilocalories), and body impedance.

For analysis data were expressed as mean ± standard deviation (SD). Quantitative variables were compared using the unpaired Student's t-test. When the assumption of normality was not met, a non-parametric test was applied (Mann–Whitney U-test). Pearson correlation coefficient or Spearman rank correlation coefficient were calculated to assess the relationships between various clinical and functional parameters in COPD patients. All statistical tests were 2-tailed, and p value < 0.05 was considered significant for all analyses.

RESULTS

We enrolled a total of 60 male subjects, of which 31 were COPD patients and 29 controls. The most important clinical and anthropometric characteristics, respiratory function and body composition data are shown in table I.

TABLE I

Clinical characteristics, respiratory function and body composition

	Case	Control	p value
Age (years)	65.77 ± 8.86	61.41 ± 8.69	0.056
Smoking (py)	37.95 ± 18.83	19.34 ± 20.23	<0.001
Weight (kg)	66.80 ±16.27	81.51 ± 16.45	<0.001
Height (cm)	168 ± 6.11	171.34 ± 6.00	0.061
BMI (kg/m^2)	23.57 ± 5.09	27.74 ± 5.26	0.001
FEV1 (%)	37.59 ± 13.47	102.28 ± 15.02	<0.001
FEV1/FVC (%)	51.87 ± 10.90	80.95 ± 7.43	<0.001
6MWT distance (m)	276.09 ± 106.68	424.2 ± 77.9	<0.001
Fat (%)	17.89 ± 8.70	18.10 ± 7.24	0.842
Fat (kg)	12.83 ± 8.11	15.45 ± 9.24	0.185
Lean (%)	81.92 ± 8.56	81.89 ± 7.24	0.750
Lean (kg)	54.44 ± 11.21	66.22 ± 10.56	<0.001
Dry lean (kg)	8.35 ± 5.50	12.86 ± 4.33	0.001
Water (%)	70.60 ± 11.19	66.48 ± 8.2	0.111
Water (L)	46.09 ± 7.08	53.15 ± 6.86	<0.001
Basal metabolism (kcal)	1626.8 ± 290.9	1915.8 ± 262.9	<0.001
Impedance	410.8 ± 69.1	357.1 ± 57.2	0.002

A higher smoking index and lower weight were found in the COPD as compared to the control group. The 6-minute walking distance was significantly higher in the control group. BMI calculation in the patients in the COPD group showed: 67% were normal weight, 10% underweight, 10% overweight and 13% obese (fig. 1).

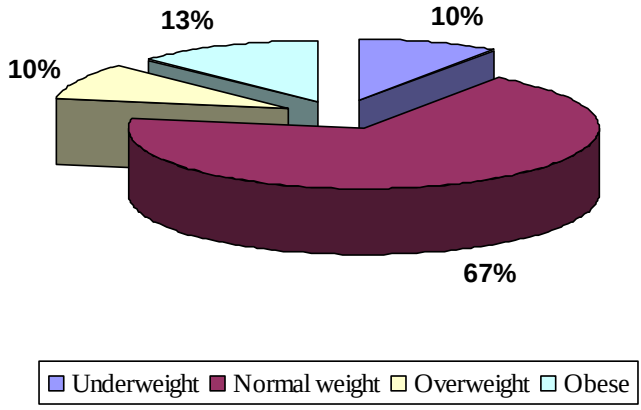

Fig. 1. Distribution of COPD patients according to BMI

The results of body composition assessment revealed certain particularities in COPD patients. The dry lean mass was significantly lower than in the healthy subjects. The absolute lean mass value, expressed in kilograms, was also lower in COPD patients, but no significant differences in percentage values between the two study groups were found.

Body water, in liters, was higher in the control compared with COPD group. However, body water percentage was higher in COPD patients than in controls, without reaching statistical significance. No difference in body fat mass, expressed either as percentage or absolute value, between COPD patients and healthy subjects was found. The different patterns of body composition determined a significant difference in body impedance between the study groups, which was significantly higher in COPD patients. Bioelectrical impedance analysis allowed the estimation of the basal metabolic rate. This was significantly higher in the control group than in COPD patients.

We also assessed the relationships between the results of body composition analysis and other clinical or functional parameters in COPD patients (tab. II).

In COPD patients, lean mass and dry lean mass, expressed in kilograms, were inversely correlated with age and dyspnea score (MMRC), and positively correlated with FEV1 and 6MWT distance (6MWTd). Body water percentage correlated with age and water volume (liters), inversely correlated with dyspnea score and positively correlated with FEV1 and 6MWTd. Basal metabolic rate, determined by bioelectrical impedance analysis, inversely correlated with age and MMRC and positively correlated with FEV1 and 6MWTd. No significant correlations between body composition components and health impairment in COPD patients, estimated by the three SGRQ component scores including symptoms, activity and impacts were found.

TABLE II

Correlations between body composition, clinical and functional parameters in COPD patients

		Age	MMRC	FEV1%	FEV1/FVC	6MWTd
Lean (kg)	Correlation Coefficient	-0.395	-0.473	0.47	0.475	0.505
	p value	0.002	<0.001	<0.001	<0.001	<0.001
Dry lean (kg)	Correlation Coefficient	-0.523	-0.398	0.361	0.402	0.474
	p value	<0.001	0.002	0.005	0.001	<0.001
Water (%)	Correlation Coefficient	0.329				
	p value	0.01				
Water (L)	Correlation Coefficient		-0.482	0.491	0.465	0.415
	p value		<0.001	<0.001	<0.001	0.001
Basal Metabolic Rate (kcal)	Correlation Coefficient	-0.37	-0.459	0.464	0.465	0.493
	p value	0.004	<0.001	<0.001	<0.001	<0.001
Impedance	Correlation Coefficient		0.392	-0.42	-0.34	-0.318
	p value		0.002	0.001		0.013

DISCUSSION

Even though the majority (67%) of COPD patients had a BMI within normal limits, the subjects in the control group presented a significantly higher BMI, which is in line with the results reported by Engelen et al. in patients with pulmonary emphysema (14).

Unlike Ischaki et al. we have proved a significant correlation of BMI, not only with 6MWTd but also with FEV1 which is the main determinant of COPD stage (15). A major difference is that, unlike previous studies, we found no differences in body fat mass between COPD patients and healthy controls and no correlation between body fat mass and clinical or functional parameters (8).

Ischaki et al. have demonstrated correlations between free-fat mass index and MRC dyspnea scale, 6MWT distance and percentage predicted FEV1 (15). Our results support these findings, proving an inverse correlation between lean mass/dry lean mass, expressed in kilograms, and dyspnea score (MMRC) and a positive correlation with FEV1 and 6MWTd. We also found a significantly lower lean mass in the COPD than in the control group.

Body water was also significantly lower in COPD patients than in healthy subjects. As lean body mass, body water inversely correlated with dyspnea score and positively correlated with FEV1 and 6MWTd. Previous researches demonstrated that COPD patients associating fat-free mass depletion are characterized by increased extracellular/intracellular water ratio (16).

Body impedance analysis also provided an estimation of the basal metabolic rate.

This was lower in COPD group, inversely correlated with age and dyspnea severity and positively correlated with FEV1 and exercise capacity. However, other researchers have used more accurate methods for assessing metabolic rate in COPD. Using indirect calorimetry adjusted for the influence of fat-free mass, Creutzberg et al. have proved that hypermetabolism commonly occurs in COPD but cannot be linked to aging and fat-free mass depletion (17).

CONCLUSIONS

Although more than a half of our COPD patients are normal weight, they may present important disturbances in body composition. Lean body mass, dry lean mass and body water are significantly lower in COPD patients than in healthy subjects. These significantly correlate with age, dyspnea, severity of airway obstruction, and exercise capacity in patients with chronic obstructive lung disease.

CONE-BEAM COMPUTED TOMOGRAPHY ANALYSIS OF THE VESTIBULAR SURGICAL PATHWAY TO THE PALATINE ROOT OF THE MAXILLARY FIRST MOLAR

Surgical endodontic treatment has been considered difficult to perform for the maxillary molars because the operative site is frequently close to important anatomical structures, such as the major palatine vascular-nervous bundle and the maxillary sinus. Therefore clear visualization of the operative area as well exact localization of the anatomic structures surrounding the area before surgery is crucial to prevent surgical complications. Cone-beam computed tomography (CBCT) has been specifically designed to produce undistorted 3D information of the maxillofacial skeleton, including the teeth and their surrounding tissues, with a significantly lower effective radiation dose as compared with conventional CT. The aim of this study was to evaluate the anatomical distance between the apices of the palatine root of the maxillary first molars to the buccal bone plate in order to identify the vestibular surgical pathway using cone-beam computed tomography (CBCT) images. CBCT scans of 107 (48 male and 59 female) patients were retrospectively analyzed. A Pearson's chi square test and Mann-Whitney U-test were performed to evaluate differences among age, localization, and measurements. Differences were considered statistically significant at $P<.05$. The mean distance between the buccal cortex and the buccal side of the palatine root of the superior first molar in both male and female patients was 10.13 and 9.70 mm, respectively. The incidence of interposition of the lateral recess of the maxillary sinus between the roots was 42.2% and 49% in men and women, respectively. Statistically significant sex-related differences were found in the vestibular surgical pathway ($P<.05$). These results suggested that CBCT could be a powerful tool for the evaluation of surgical cases and identification of the most appropriate surgical pathway. However the authors point out that CBCT images should not necessarily replace conventional radiographic images when there is no need for a surgical procedure to eliminate infected tissues by resecting the root apices (Kalender A, Aksoy U, Basmaci F, Orhan K, Orhan AI**:** Cone-beam computed tomography analysis of the vestibular surgical pathway to the palatine root of the maxillary first molar. *Eur J Dent* 2013; 7(1): 35-40).

SIGNIFICANCE OF ARTERIAL STIFFNESS AND RELATIONSHIP WITH OTHER NONINVASIVE METHODS FOR THE ASSESSMENT OF SUBCLINICAL ATHEROSCLEROSIS IN PATIENTS WITH METABOLIC SYNDROME (Abstract): Measurement of arterial stiffness is an accurate method of assessment of endothelial dysfunction, together with other noninvasive methods, in the diagnosis of atherosclerotic burden in patients with MetS. **Material and methods**: The study included 63 patients: MetS group (18 men, 20 women, mean age 58.86±8.86 years) and the control group (14 men, 11 women, mean age 59.68±10.0 years). They underwent the following examinations: assessment of arterial stiffness - pulse wave velocity (PWVao), augmentation index of brachial artery (Aixbr) and aorta (Aixao), central systolic blood pressure (SBPao); carotid ultrasound for detection of plaques and measurement of intima-media thickness (IMT); echocardiography - left ventricular hypertrophy (LVH); ankle-brachial index (ABI); biochemical parameters: C-reactive protein (CRP), fibrinogen (Fb), cholesterol (Col), HDLcol, LDLcol and triglycerides. **Results**: MetS patients had higher PWVao (10.06±2.12 m/s vs 8.29±1.33 m/s, p=0.0001) and SBPao (135.06±19.80 mmHg vs. 121.76±18.62 mmHg, p=0.009). Carotid IMT was higher in MetS group (0.92±0.11 vs. 0.83±0.10 mm, p=0.003). Almost all MetS patients were hypertensive (94.7% vs. 52%, p=0.01); LVH was present in 57.9% of MetS patients and 20% of the controls (p=0.05). The MetS group presented higher Col (208.76±38.41 vs. 176.20±30.08 mg/dl, p=0.0003) and CRP levels (0.872±0.852 mg/dl vs. 0.476±0.392 mg/dl, p=0.01). **Conclusions**: In MetS patients the most reliable marker of arterial stiffness was PWVao, followed by SBPao. Higher values of carotid IMT are also parameters of high atherosclerotic risk. CRP and Col can be considered biomarkers of high risk in MetS. **Keywords**: METABOLIC SYNDROME, ARTERIAL STIFFNESS, SUBCLINICAL ATHEROSCLEROSIS.

Metabolic syndrome (MetS) consists in a constellation of cardiovascular risk factors with a direct impact on the initiation and progression of atherosclerotic cardiovascular disease. Several large studies showed that subjects with MetS are prone to adverse cardiovascular events. Such a patient is vulnerable, prone to acute coro-

nary syndrome, sudden death, or stroke, due to vulnerable atherosclerotic plaque (prone to disruption or thrombosis), vulnerable blood (prone to thrombosis) or vulnerable myocardium (prone to arrhythmia) (1, 2, 3).

The present cardiovascular risk charts, as Framingham in the U.S.A. or SCORE in Europe, can identify subjects at very high risk or low risk of cardiovascular events in the next ten years (4, 5). Yet, there are a large number of subjects with an intermediate risk score, often underestimated by the risk charts. In this group of individuals, noninvasive detection of asymptomatic atherosclerosis is indicated, before the occurrence of major adverse events (6, 7). The investigations suggest that carotid ultrasound (CU), ankle-brachial index (ABI), cardiac CT for calcium scoring, or magnetic resonance imaging is useful in detecting subclinical atherosclerosis. While ABI, intima-media thickness (IMT) and carotid plaque ultrasound assessment are widely used, the other two are less available. The measurement of arterial stiffness provides additional useful information in the evaluation of atherosclerotic risk together with the above mentioned noninvasive methods (8).

The aims of the study are: - assessment of arterial stiffness in patients with MetS by measuring aortic pulse wave velocity (PWV) as the gold standard for assessing arterial stiffness; - importance of arterial stiffness analysis as a parameter of cardiovascular risk in MetS; - significance of other noninvasive methods for the detection of subclinical atherosclerosis and some biochemical markers in MetS.

MATERIAL AND METHODS

The study included 38 patients with MetS (18 men, 20 women), group S, and 25 control patients (14 men, 11 women) – group C. Patients in group S met the MetS criteria according to ATP III: fasting glucose $\geq$ 110 mg/dl or known type 2 diabetes mellitus (type 2 DM); waist circumference (WC) $\geq$ 102 cm in men and $\geq$ 88 cm in women; serum triglycerides $\geq$ 150 mg/dl; HDL $<$ 40 mg/dl in men and $<$ 50 mg/dl in women; arterial pressure $\geq$ 130/85 mmHg or treatment for arterial hypertension (AHT). Patients were included in group C when at least three MetS criteria were not present.

The exclusion criteria were: secondary AHT, significant chronic renal disease, major cardiovascular complications (myocardial infarction, stroke, heart failure, cardiac or peripheral revascularization).

The following investigations were made: medical history and clinical examination; electrocardiography; ABI. Echocardiography studied markers of left ventricular hypertrophy (LVH), systolic and diastolic function, aortic and valvular atherosclerosis. CU measured IMT of the distal common carotid artery and bifurcation and revealed atherosclerotic plaques. The echographic examinations were performed with an Esaote MyLab50. The biochemical tests included determinations of fasting blood glucose, cholesterol (Col), HDL cholesterol, triglycerides (TG), calculation of LDL cholesterol with the formula Col – HDL – TG/5, C reactive protein (CRP), fibrinogen (Fb), plasma urea and creatinine, hepatic enzymes - alaninaminotransferase (ALAT), aspartataminotransferase (ASAT).

Arterial stiffness was assessed by a TensioMedArteriograph TL2. The following parameters were measured: brachial augmentation index (AIXbr), aortic augmentation index (AIXao), aortic pulse wave velocity (PWVao), central pulse pres-

sure (PPao), and systolic blood pressure (SBPao).

Statistical analysis was performed in *SPSS 11.0* software. The mean values, frequencies, standard deviations were calculated. *"t"* Student test was used to assess the significance of difference between two mean values; chi square test was used to analyze the difference between two frequencies.

RESULTS

Mean age of group S was 58.86 ± 8.86 years, and of group C 59.68 ± 10.0 years, age-matched controls.

Anthropometric data. In all group S patients WC was above the maximum admitted values, with a mean of 109.05 ± 9.53 cm in men and 110.10 ± 15.48 cm in women. In group C, mean WC was significantly lower (p=0.006). In group C most subjects were normal weight (36%) or overweight (32%), whereas in group S most were overweight (28.95%) or obese (68.42%) (tab. I).

TABLE I

General and anthropometric data in the two study groups

Parameter	Group S	Group C	P
Age (years) (mean ± SD)	58.86 ± 8.86	59.68 ± 10.0	NS
Male gender (nr, %)	18 (47.4%)	14 (56%)	NS
Weight (kg)	90.89 ± 17.03	73.76 ± 20.51	0.001
BMI (W/H^2)	33.36 ± 6.61	26.36 ± 6.33	NS
Waist circumference in men (cm)	109.05 ± 9.53	92 ± 18.88	0.006
Waist circumference in women (cm)	110.10 ± 15.48	94.54 ± 10.15	0.002

Analysis of *arterial stiffness parameters* showed that PWVao was 10.06 m/s in group S, and significantly lower (p=0.0001), 8.29 m/s, in group C. According to the reference values, in 64% of the controls it was optimal, in the remaining 36% being normal or elevated. In group S, in 50% it was normal, in 34.2% elevated and in 13.1% pathologic, above 12 m/s (with a maximum of 17.1 m/s) (fig. 1).

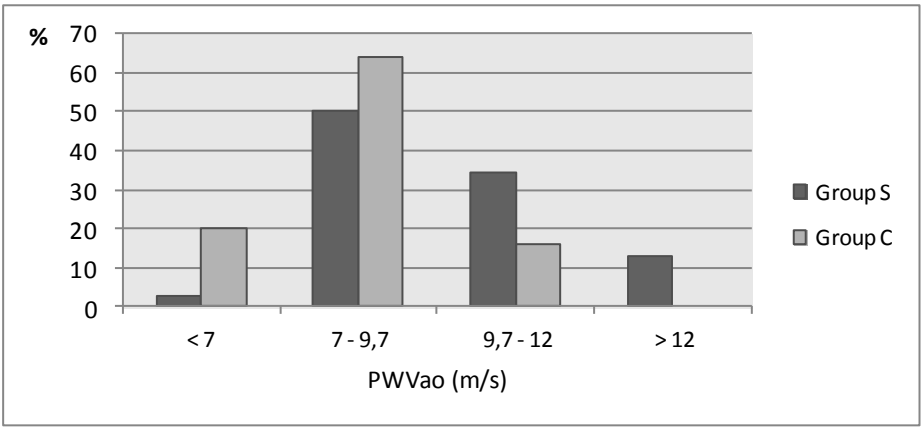

Fig. 1. The prevalence of PWVao according to value categories

SBPao in group S was 135.06 mmHg, higher than in group C (121.76 mmHg, p=0.009). There were no significant differences in AIXbr and AIXao between the two groups (tab. II).

Carotid intima-media thickness (IMT) in group S was 0.92 ± 0.11 mm, significantly higher than in the C group (0.83 ± 0.10 mm, p=0.003) (tab. II). *Carotid plaques* were present in both groups, more frequent in group S (86.8%) compared with C group (72%), but without statistical significance.

Mean values of *ABI* were not significantly different, but the analysis showed that in group S 9 patients (23.68%) had values outside the normal range (0.9 – 1.3) compared with only two subjects in group C (8%) (tab. II).

AHT was present in almost all group S (94.7%) and less in group C patients (52%, p=0.01). LVH was defined in the presence of a left ventricular mass index (LVMI) above 122 g/m^2 in women and 149 g/m^2 in men. LVH was found in 57.9% of the patients with MetS*versus* 20% in the controls (p=0.05) (fig. 2).

Echocardiography revealed *aortic atherosclerotic alterations* in almost all patients with MetS (97.4%), and in most controls (80%). Diastolic dysfunction, assessed by E/A ratio < 0.9, was present in 68.4% group S and 52% group C patients (fig. 2).

Type 2 DM, another component of MetS, was found in 42% of group S patients. No subject in group C had type 2

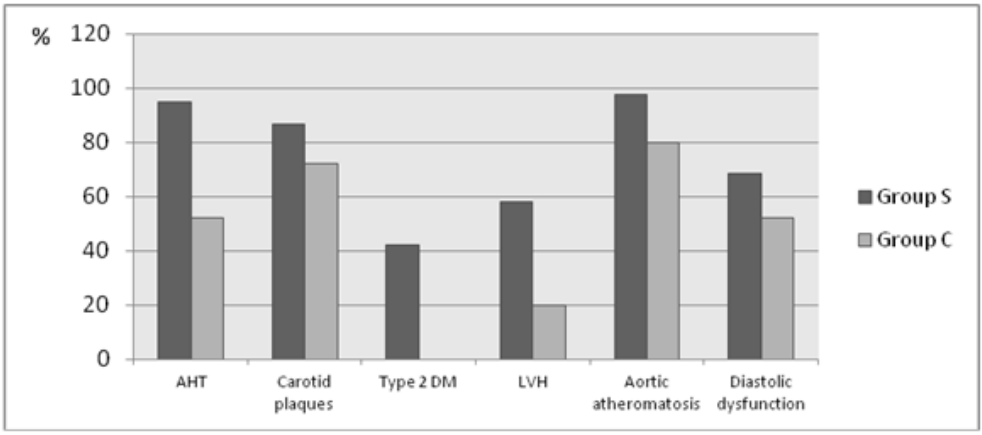

Fig. 2. Prevalence of different parameters in the two study groups

Analysis of *serum lipids* showed the following. In group S, 63% presented Col levels above 190 mg/dl, compared with 32% in group C, with mean values higher in group S. HDL was slightly higher in group S. Triglycerides were also higher in group S but without statistical significance (tab. II).

The studied *inflammation markers* were C reactive protein (CRP) and serum fibrinogen (Fb). CRP levels higher than 1 mg/l were found in 44% in group S and in only 16% in group C; no differences in Fb levels were found between the two groups (tab. II). When comparing the hepatic enzymes levels, higher ALAT values were found in group S, with ASAT values were similar in the two groups (tab. II).

TABLE II
Imaging and biochemical data in the two study groups

Parameter	Group S	Group C	p
PWVao (m/s)	10.06 ± 2.12	8.29 ± 1.33	0.0001
SBPao (mmHg)	135.06 ± 19.80	121.76 ± 18.62	0.009
AIXbr (%)	10.99 ± 24.28	10.54 ± 37.44	NS
AIXao (%)	42.03 ± 12.76	42.92 ± 18.96	NS
Carotid IMT (mm)	0.92 ± 0.11	0.83 ± 0.10	0.0063
Cholesterol (mg/dl)	208.76 ± 38.41	176.20 ± 30.08	0.0003
HDL col (mg/dl)	54.56 ± 13.52	50.08 ± 7.98	NS
LDL col (mg/dl)	114.08 ± 34.03	103.08 ± 27.88	NS
Triglycerides (mg/dl)	199.16 ± 100.01	115.96 ± 40.42	NS
CRP (mg/l)	0.87 ± 0.85	0.47 ± 0.59	NS
Fibrinogen (mg/dl)	367.78 ± 85.71	336.08 ± 46.94	NS
ABI	1.11 ± 0.18	1.08 ± 0.11	NS
ALAT (UI)	39.41 ± 19.36	28.44 ± 9.89	0.004
ASAT (UI)	29.14 ± 19.81	25.72 ± 12.34	NS

DISCUSSION

The analysis of the clinical and biochemical features related to the criteria used to define MetS showed, as expected, higher WC and BMI in the MetS group. WC is a better predictor of cardiometabolic risk than BMI. Type 2 DM was present in about half of MetS group and this could be explained by insulin resistance. The risk of developing DM is three times higher in MetS compared to general population. AHT was present in almost all MetS patients and it doubled the cardiovascular risk (9).

The assessment of asymptomatic atherosclerosis by the noninvasive methods described in the study showed some peculiarities. LVH is more frequent in MetS and is an independent cardiovascular risk factor (10). IMT is another marker of atherosclerosis, together with carotid plaques, and their presence has to be interpreted as atherosclerotic disease, even if asymptomatic and adequate measures must be taken (11).

Mean serum cholesterol is higher in MetS patients and increases cardio metabolic risk. In this study there were not significant differences in HDL and TG between the two groups; this can be partially explained by the relative small groups, but also by the fact that most patients were under hypolipemiant treatment. The finding of higher CRP levels is in agreement with other studies that showed a correlation between the inflammation markers and MetS (12).

Focusing on the results of arterial stiffness in MetS patients, it could be asserted that PWVao is the parameter that correlates best with the presence of MetS, followed by SBPao. The differences between groups could be explained in part by the higher prevalence of AHT in the MetS group. Arterial stiffness is known to be a marker of early endothelial dysfunction, which is influenced by several factors, not only by elevated arterial pressure levels (13). AIXbr and AIXao are mentioned in studies as indicators of arterial stiffness and cardi-

ovascular risk; in the present study they did not prove to have diagnostic significance.

CONCLUSIONS

Increased arterial stiffness is an early finding in patients with MetS compared with controls. The most reliable parameter is PWVao, followed by SBPao; AIXbr and AIXao have a less predictive value.

Other markers of early atherosclerosis in MetS are carotid IMT and LVH. Of the biochemical investigations, CRP and cholesterol have better predictive value while LDL and TG have less predictive value.

THE RISK OF THROMBOTIC EVENTS IN PATIENTS WITH LIVER CIRRHOSIS (Abstract). **Aim**: To evaluate the incidence and risk factors for thrombotic events (deep vein thrombosis and portal vein thrombosis) in patients with liver cirrhosis. **Material and methods**: we studied patients diagnosed with liver cirrhosis admitted in our department between January 2010-December 2011, which were divided in two groups: liver cirrhosis with thrombotic events and without thrombotic events. **Results**: we included 3108 patients, the incidence of deep vein thrombosis was 0.99% and portal vein thrombosis was 1.51%, the incidence of all thrombotic events was 2.5%. In the univariate analysis serum albumin was significantly lower in cases than controls, and MELD score, mean platelet volume were higher in cases than controls. The presence of sepsis and diabetes mellitus were demonstrated like risk factors by the univariate analysis. In multivariate analysis, albumin level< 3mg/dl (HR=1.65, CI 1.10-2.51, p=0.018) and MELD score >13 (HR=2.94, CI 1.61-5.47, p=0.001) remained independently predictive of thrombotic events. **Conclusions**: The incidence of thrombotic events in patients with liver cirrhosis was 2.5%. Low serum albumin and high MELD score could predict the development of thrombotic events in patients with liver cirrhosis. **Keywords**: DEEP VEIN THROMBOSIS, PORTAL VEIN THROMBOSIS, LIVER CIRRHOSIS, RISK.

In the last years, the axiom that says that the patient with liver cirrhosis is predisposed to bleeding has proved to be wrong (1). The influence of liver disease on hemostasis is complex, the changes being determined by lower serum levels of both procoagulant and anticoagulant factors, especially in the advanced stages of liver cirrhosis (2).

In cirrhotic patients also, the pathogenesis of venous thrombosis is based on Virchow's triad: venous stasis, hypercoagulability, and venous injury. In portal vein thrombosis (PVT) venous stasis is caused by the decreased portal flow as a consequences of portal hypertension (3), and in cirrhotic patients with deep vein thrombosis (DVT) limited physical activity along with advanced liver cirrhosis are leading to venous stasis and thrombosis. Procoagulant status in cirrhotic patients is characterized by low anticoagulant factors (protein C,

protein S, antithrombin III), and high values of factor VIII and von Willenbrand factor (4). Endothelial dysfunction associated with cirrhosis is based on increased nitric oxide and proinflammatory cytokines and contributes to vascular wall damage and increases the risk of thrombosis (4).

The accumulation of thrombotic risk factors results in an incidence of DVT in cirrhotic patients ranging from 0.9 to 1.8%, increasing to 8.1% in hospitalized patients (5-7), while the incidence of PVT is 1% in patients with compensated liver cirrhosis, reaching 25% in those on the liver transplant list (3).

Although the cirrhotic patient is no longer considered "anticoagulated" (8), his thrombotic risk being similar to that in general population (9), the American College of Chest Physicians (ACCP) does not specify prophylactic measures and a curative treatment of thrombosis in this population (9), due to the lack of concrete data on the risk factors associated with thrombosis and the impossibility to assess the risk of bleeding associated with anticoagulant therapy.

The aim of this study was to determine the incidence and risk factors associated with venous thrombosis in hospitalized patients diagnosed with liver cirrhosis.

MATERIAL AND METHODS

In the study we enrolled patients admitted to the Center of Gastroenterology and Hepatology Iasi between January 2010 and December 2011, who were diagnosed with liver cirrhosis.

Exclusion criteria were previous diagnosis of hereditary thrombophilia, hepatocellular carcinoma or other known malignancies and patients on anti-coagulation or antiplatelet therapy.

The diagnosis of liver cirrhosis was made on clinical manifestations, biological, endoscopic and ultrasound changes suggestive for advanced liver disease and portal hypertension, and confirmed, in some cases, by elastography (Fibroscan), a non-invasive method for the assessment of liver fibrosis.

Thrombotic events, defined as deep vein thrombosis and portal vein thrombosis, were diagnosed clinically and confirmed by venous Doppler ultrasound for DVT and abdominal ultrasonography and contrast computer tomography for PVT.

Liver cirrhosis severity was evaluated using the MELD score (Model of End Life Disease) and Child-Pugh score which is based upon the presence of ascites, hepatic encephalopathy, serum bilirubin, INR and serum albumin levels.

To determine the thrombotic risk factors, the group of patients diagnosed with venous thrombosis was compared with a control group of cirrhotic patients without thrombotic events, randomly selected from all cirrhotic patients admitted during the above mentioned interval.

Statistical analysis was performed using SPSS 17.0 (SPSS, Inc., Chicago, IL). For comparing the two groups Chi-square test for categorical variables and *t* Student test for numeric values were used. The thrombotic risk factors were determined using logistic regression for univariate analysis, and Cox regression analysis method for multivariate analysis.

RESULTS

Out of the 3108 patients included in the study, 31 patients were diagnosed with DVT and 47 patients with PVT, which corresponds to a 2.5% incidence of thrombotic events in patients diagnosed with

liver cirrhosis, 0.99% for DVT and 1.51% for PVT.

DVT was located in the calf in 28 patients, 3 patients had ileo-femoral DVT; the right leg was the most frequently affected, 58% of cases (18 patients).

In 56% of cases PVT was complete and 5 cases were diagnosed with portal cavernoma. Excluding the 5 cases diagnosed with portal cavernoma, imaging evaluation by Doppler ultrasound and CT could not establish the age of portal vein thrombosis.

None of the patients diagnosed with DVT or PVT had a history of recent surgery (less than one month) or prolonged immobilization.

Out of the 3,030 patients with liver cirrhosis without thrombotic events we have randomly selected a control group of 160 patients in order to establish the risk factors involved in the occurrence of DVT and PVT.

The two groups were comparable in terms of demographic characteristics (age, sex), but the group with thrombotic events was characterized by a higher MELD score ($p < 0.0001$), a higher prevalence of Child-Pugh classes B and C, presence of ascites ($p = 0.083$), hypoalbuminemia ($p = 0.005$), sepsis ($p < 0.0001$), mean platelet volume (MPV) increased ($p < 0.0001$), and diabetes mellitus ($p = 0.008$) (tab. I).

TABLE I

Clinical and biological characteristics of the study groups

Univariate analysis identified as risk factors for the development of thrombotic events: MELD score>13, albumin <3mg/dl, VPM> 10.5 fl, presence of sepsis and diabetes mellitus (tab. II); the remaining clinical and biological parameters did not reach statistical significance.

Of the above mentioned factors, multi-

variate analysis has confirmed as independent risk factors of thrombosis in cirrhotic patients: albumin <3 mg/dl, and the presence of sepsis, as a reflection of their advanced liver disease (tab. III).

None of the patients with DVT was diagnosed with pulmonary embolism based on clinical symptoms, but asymptomatic pulmonary embolism has not been evaluated.

TABLE II

DISCUSSION

So far there are several studies that have attempted to assess the thrombotic risk in cirrhotic patients, and some of the results are contradictory.

A population-based study conducted in Denmark on 99,000 patients showed that cirrhotic patients have a 1.74 times higher risk of developing DVT than the general population (10), and the risk was 2.10 times higher in patients aged <55 years. These data, however, were not confirmed by the results of a smaller case-controlled study, carried out by Heit et al., which demonstrated that the association of liver cirrhosis in general population reduced the risk of thrombotic events (RR 0.10) (11). The two studies had some limits because they were not aimed primarily to assess thrombotic events in cirrhotic patients, and the data were extracted from a study subanalysis, so that their relevance is low.

DVT incidence in cirrhotic patients was assessed in eight studies, including two case-control and six retrospective studies, the reported incidence of DVT in cirrhotic patients ranging between 0.5 and 8.1% (5, 7, 12, 13). In our study the incidence of DVT was 0.9%, similar to data reported in the literature.

Non-malignant portal vein thrombosis in cirrhotic patients has an incidence of 5-

26% (3). The incidence of 1.51% found in our study was lower than that reported in the literature, but it must be mentioned that previous studies have been conducted in patients on liver transplantation list, diagnosed with advanced liver cirrhosis .

Although surgical interventions and prolonged immobilization are major risk factors for the development DVT in the general population (9), in our study no patient diagnosed with DVT or PVT had a history of recent surgical intervention or prolonged immobilization, supporting the hypothesis that the risk factors involved in the occurrence of thrombosis in cirrhotic patients are different from the general population.

Our study showed that sepsis is a risk factor for the development of thrombotic events in patients with cirrhosis, confirming the results of the study conducted by Garcia-Fuster et al, in which 6 of the 17 patients with DVT were diagnosed with sepsis (6). Sepsis acts by increasing the direct effect of proinflammatory cytokines, vascular endothelial damage, and also by stimulating platelet aggregation (14). It has been shown that coagulation disorder, defined by elongation of prothrombin time and INR, does not predict the risk of bleeding in cirrhotic patients and does not reflect the true coagulation status in this population (1); moreover they do not protect patients from the occurrence of thrombotic events (5,15). In our study, INR values, prothrombin time, as well as platelet count were similar in the two groups. The difference between the two groups occurred when we used mean platelet volume as a method for assessing platelet trombogenity. MPV was higher in patients with thrombotic events, and univariate analysis recognized MPV as a thrombotic risk factor. Mean platelet volume is used to assess the risk for thrombosis in patients with ischemic heart disease (16), without being used, until now, in cirrhotic patients. The role of MPV in these patients remains to be established.

Of the biological parameters used to evaluate cirrhotic patients only albumin level <3mg/dl was an independent risk factor for the development of thrombotic events, and reflected poor protein synthesis, including anticoagulant factors (protein C, protein S, antithrombin III).

This is the first national study on the incidence of thrombotic events in patients with cirrhosis and the first in which mean platelet volume as a risk factor for thrombosis in patients with liver cirrhosis was used.

The development of a thrombotic risk scale and a method for the assessment of bleeding risk are essential in DVT and PVT prophylaxis and curative treatment in patients with liver cirrhosis.

CONCLUSIONS

The incidence of thrombotic events in patients with cirrhosis was 2.5%, confirming that this population is not "anticoagulated" by definition.

Cirrhotic patients with serum albumin level <3mg/dl and MELD score> 13 have an increased risk for developing thrombotic events, correlated with the severity of liver disease. Thrombosis prophylaxis should be considered in the management of cirrhotic patients and the current guidelines for thromboprophylaxis should also include this special patient category.

ANTIBIOTIC THERAPY IN SEVERE SEPSIS IN HIV-POSITIVE PATIENTS (Abstract): Severe sepsis has become one of the most frequent causes of hospitalization in intensive care units for patients diagnosed with HIV infection. The difficulty in setting a sepsis diagnosis in HIV-positive patients led to the systematic exclusion of these patients from studies on sepsis, which limited the understanding of its impact on the evolution of the disease. Our study aims to evaluate the etiology of sepsis in immunocompromised HIV-positive patients and the evolution after antibiotic therapy. 30 patients diagnosed with HIV infection and sepsis, admitted to our clinic between January 2008 and April 2012, were followed. Severity of illness, time since diagnosis, CD4 count, antiretroviral treatment, incidence of severe sepsis, and organ dysfunctions were registered. Patients were between 1 and 61 years of age, most of them were classified into stages B2, B3 and C3, requiring hospitalization for a period ranging from 14 to 28 days, with an average of 16.7 days and a median of 18 days, while 8 required monitoring in the intensive care unit. In about 40% of cases, the starting point was an infection of the lower respiratory tract, but also of the upper urinary tract and skin infections. Evolution and mortality in sepsis associated with HIV/AIDS infection depend on the presence of organ failure and are less influenced by the level of immunodepression, complex antibiotic therapy being the cornerstone in controlling patients. **Key words**: HIV INFECTION, SEPSIS, ORGAN FALURE, ANTIBIOTIC THERAPY

In the past 20 years, long term survival in HIV-positive patients has been marked by the introduction of the HAART therapy and it is expected that the number of infected persons should increase, especially in developing countries, but also in the so called "third world" countries (1).

Recent studies carried on HIV-positive patients have analyzed the characteristics of critical stages, comparing pre- and post-HAART moments and focusing on the hospitalization reasons and mortality risk factors (2). Analysis of HIV infection in critical patients showed that sepsis is among the causes of hospitalization in intensive care units with a rising incidence, contrary to the decreasing tendency observed in patients with acute respiratory failure (3). Other studies proved that bacterial infections became more frequent in HIV patients irrespective of HAART use (4).

Despite a significant growth of the sur-

vival rate and the quality of life, patients with HIV/AIDS have been systematically excluded from studies focused on sepsis, thus limiting the understanding concerning the impact that the association of the two entities has in the population, and, up to now, few studies have prospectively evaluated the determinant factors in the survival of such patients (4).

Different anomalies detected in the HIV/AIDS infection defense mechanisms could account for the presence of bacterial infections with germs developing intracellularly or with encapsulated germs. These infections are also very common because of the frequent use of antibiotics and invasive procedures during repeated hospitalization.

The latest evaluations made on cohorts demonstrated that severe sepsis is a risk factor for intrahospital mortality affecting survival in the short and long term in HIV-positive patients. Mortality has rather depended on the critical status associated to the severity of organ failure than on the modifications caused by HIV/AIDS infection, irrespective of the immunodeficiency level, HAART use or the time when the HIV infection was diagnosed. Thus, death due to severe sepsis associated to HIV/AIDS infection was found by studies to range from 28 to 56 % (5).

MATERIAL AND METHODS

We have carried out a retrospective study on HIV-positive patients diagnosed with sepsis, hospitalized in the Clinical Hospital of Infectious Diseases of Iaşi, between January 2008 and April 2012.

Criteria for a sepsis diagnosis were given by the association of at least two of the following modifications: temperature>38ºC or temperature < 36ºC, cardiac frequency > 120/minute, systolic arterial pressure < 110 mmHg, respiratory frequency > 30/min, leukocytosis > 12.000/mm³ or < 4000/mm³ with the risk of aggravation should a portal of entry be identified, pulmonary or intra-abdominal, with the association of thrombocytopenia < 150.000/mm³, hypernatremia > 145mmol/l or bilirubinemia > 50mg‰.

We analyzed the clinical characteristics, context of immunodepression, and criteria of circumscription to sepsis, period and evolution under antibiotics therapy by means of APACHE II scoring evaluation.

Upon hospitalization, patients gave their written consent for their personal data to be used for scientific purposes.

RESULTS AND DISCUSSIONS

Out of 2028 HIV-positive patients hospitalized in the Clinical Hospital of Infectious Diseases of Iaşi in the above mentioned period, 30 met the sepsis diagnosis criteria. These 30 patients were aged from 1 to 61 years, with an average age of 35.6, a median of 34 years and the predominant age (module) of 32 years.

The analysis of distribution by sex showed a prevalence of the female sex (17 cases), whereas the place of residence was mainly rural (22 cases).

Patient classification according to their immunodepression stage upon hospitalization are registered in table I.

TABLE I

Patient stage of immunodepression

HIV stage	Number of patients
A3	3
B2 and B3	10
C3	17

According to whether the etiologic agent involved in the outbreak of sepsis was identified or not, three large groups of

patients were distinguished:

I. Patients with sepsis of unspecified etiology;

II. Sepsis patients with *Staphylococcus aureus Meti-R*, or with other *Gram positive* bacteria, of whom 3 cases with cutaneous staphylococci as starting point

2 cases with face staphylococci;

1 case with left chronic suppurative hemimandible as starting point;

1 case with incised palatine abscess;

III. Group of patients with sepsis originating in the urinary tract associated with urinary infection caused by *Escherichia coli*, and renal microlithiasis in 3 patients, in whom *Escherichia coli* sepsis was also present and originated in the lungs (2 cases).

Complex large spectrum antibiotic therapy, based on the principle of de-escalation, was preferred in all the three groups identified. First intention antibiotic therapy was mostly empirical and recommended from the very first signs of evolution to sepsis in HIV patients. Whenever the etiologic agent was identified, the antibiotic scheme was adjusted according to the bacterial sensitivity test to antibiotics (tab. II).

TABLE II

Antibiotic scheme

1st Group of patients	Cephalosporins GIII + Aminoglycosides Carbapenems + Quinolons
2nd Group of patients	Oxazolidinons (Linesolid) + Quinolons Lincosamides (Clindamycin) + Quinolons
3rd Group of patients	Cephalosporins GIII + Quinolons Carbapenems + Quinolons

Here are the associated diseases in the studied patients:

- infection of the lower respiratory tract (12 cases)
- thrombocytopenia (5)
- HIV encephalopathy (4)
- decompensated hepatic cirrhosis of different etiologies(4)
- oropharyngeal candidiasis (4)
- microcytic hypochromic anemia (4)
- hepato-renal failure (3)
- chemical polyradiculoneuritis (3)
- chronic prurigo (3)
- diabetes mellitus (2)
- mononucleosis syndrome (2)
- toxoplasmosis (2)
- chronic heart failure (2)

Overall, 8 patients needed monitoring in the intensive care unit, in 4 of whom the etiologic agent was identified in blood cultures (2 *Staphylococcus aureus Meti-R* cases and 2 *Escherichia coli* cases) (table III).

TABLE III

APACHE II Scoring according to the etiological agent

Germ type	<20	20-29	>30
	NUMBER OF PATIENTS		
known	2	2	0
unknown	20	4	2

Patients in the intensive care unit had an average hospitalization period of 17.4 days with defervescence occurring after 4.7 days of the average.

In patients in whom the etiologic agent was identified defervescence occurred after

an average period of 3.2 days, as compared to 3.7 days in those with unknown etiologic agent, whereas 9 became afebrile. The hospitalization period ranged between 16 and 28 days, with an average of 16.5 days and a median of 17 days.

The paraclinical evaluations revealed:

- leukocytosis >12.000/mm³ in 16 cases, leukopenia<4000/mm³ in 4 patients; agranulocytosis associated with the most typical proteiform clinical presentation and the longest periods of hospitalization (between 23 and 28 days);
- the hepatic function underwent deterioration in 6 cases, the maximum transaminases levels reaching 2580 UI/L for TGP and 1750 UI/L for TGO;
- a hepato-renal syndrome was present in 3 cases, in 2 of whom the disease evolved towards death;
- the lymphocytes TCD4 level evaluated at the beginning of the antibiotic therapy varied; thus, in 12 patients, the lymphocytes TCD4 level decreased by 20-75 units during sepsis evolution.

CONCLUSIONS

Evolution and mortality rates in sepsis associated with HIV/AIDS infection depend on the presence of organ failure and are less influenced by the level of immunodepression, complex antibiotic therapy being the cornerstone in controlling patients.

Even though the identified number of cases in which sepsis was associated with HIV was relatively low in our study, additional effort is required in approaching these patients, considering their chronicization profile in the evolution of the HIV infection and, consequently, their exposure to recurring infections.

PREVALENCE OF CARDIOVASCULAR DISEASES TO THE PATIENTS WITH HYPOTHYROIDISM (Abstract): The cardiovascular risk in patients with hypothyroidism is related to an increased risk of functional cardiovascular abnormalities and atherosclerosis**. Aims** – The purpose of the present study was to examine a possible association between subclinical and clinical hypothyroidism and cardiovascular disease (CVD). The retrospective study, which covered a 12 months period, had the purpose to establish the prevalence of various risk factors for CVD, within subclinical and clinical hypothyroidism. **Material and methods**: We have studied 64 subjects with subclinical and clinical hypothyroidism admitted to the Rehabilitation Hospital, in the Cardiovascular Clinic. They were divided by sex, age, living environment (urban, rural), value of cholesterol, heart rate, BMI, blood pressure. **Conclusions** - The study revealed an increased risk of cardiovascular abnormalities and an increased risk of atherosclerosis: 65,61% subjects were obese, 90,6% with high blood pressure, 62,5% had dyslipidaemia. Subclinical thyroid dysfunction is common in older people. The identification of subclinical and clinical hypothyroidism earlier, pursuit of markers for subclinical atherosclerosis and deployment of lifestyle changes, are elements that can also be the key in improving clinical and paraclinical parameters. **Key words**: SUBCLINICAL HYPOTHYROIDISM, CLINICAL HYPOTHYROIDISM, CARDIOVASCULAR ABNORMALITIES, ATHEROSCLEROSIS

Hipotiroidismul se caracterizează printr-o producție scăzută de hormoni tiroidieni la nivelul glandei tiroide, ce se traduce printr-o concentrație scăzută a hormonilor la nivelul celulelor şi țesuturilor, şi poate varia ca severitate de la forma uşoară (mild subclinical hypotiroidism-SCH) până la cea mai severă, respectiv mixedemul (1). Sistemul cardiovascular este una din principalele ținte de acțiune ale hormonilor tiroidieni, şi în acelaşi timp un marker sensibil al acțiunii periferice a acestora (2). Riscul cardiovascular la pacienții cu hipotiroidism este determinat atât de modificări la nivelul sistemului cardiovascular, cât şi de modificările aterosclerotice. La nivelul sistemului cardiovascular sunt menționate favorizarea şi apariția disfuncției endoteliale, afectarea atât a funcției sistolice, cât şi a celei diastolice globale, în special la nivelul ventriculului stâng, creşterea rezistenței arteriale periferice cu scădere toleranței la efort. Creşterea riscului

aterosclerotic rezultă din predispoziția spre HTA (şi în special HT diastolică) şi modificarea profilului lipdic (3). T3 inflențează frecvența cardiacă, funcția sistolică, diastolică şi rezistența vasculară sistemică, ducând la scăderea performanței cardiace şi tulburări la nivelu contractilității miocardului. De asemenea la pacienții cu hipotiroidie se constată o scădere a presarcinii, cu scăderea volumului total circulant şi a funcției diastolice chiar la niveluri incipiente ale hipotiroidiei (4). Rezistența vasculară periferică şi timpul de circulație crescute se asociază cu redistribuția fluxului sanguin, scăderea fluxului plasmatic renal, concentrația plasmatică a reninei şi aldosteronului scăzute. În acelaşi timp, apariția disfuncției endoteliale favorizează atât procesul aterosclerotic cât şi rigiditatea arterială, ceea ce va contribui la accentuarea HTA în contextul hipotiroidismului (5).

MATERIAL ŞI METODE

Studiul şi-a propus cuantificarea bolilor cardiovasculare, cât şi a factorilor de risc cardiovasculari cu valoare predictivă asupra morbidității şi mortalității prin boli cardiovasculare, la pacienții cu hipotiroidie internați în Clinica de Recuperare Cardiovasculară. Din numărul total de pacienți internați în Clinica de Recuperare Cardiovasculară a Spitalului de Recuperare Iaşi în perioada 1.01.2011-1.01.2012 au fost incluşi în studiu 64 pacienți cu diagnostic confirmat de hipotiroidism. S-a urmărit distribuția acestor pacienți în funcție de mediul de proveniență, indicele de masă corporală (IMC), circumferința abdominală, colesterolul, TA, frecvența cardiacă, modificările ecocardiografice, diagnosticele la externare.

REZULTATE

În lotul de studiu, din cei 64 pacienți, 90% (58) pacienți au avut vârsta peste 50 ani, 63 (98,4%) au fost femei şi 1 (1,5%) bărbat (diferență semnificativă statistic între cele 2 loturi, $p<0.01$), distribuția pe mediul de proveniență fiind: 46 (72%) din mediul urban şi 18 (28%) din mediul rural (diferența semnificativă statistic se păstrează şi între medii, $p<0.01$) (fig. 1).

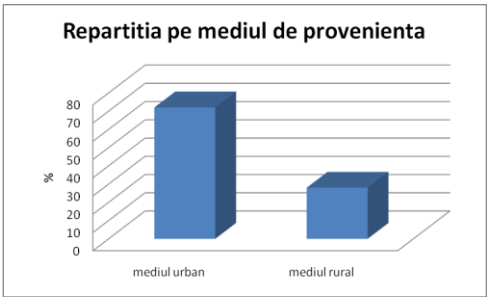

Fig. 1. Repartiția pacienților pe mediul de proveniență

În funcție de IMC (indice de masă corporală), repartiția pacienților a fost următoarea: 5 (7,85%) normoponderali, 17 (26,5%) supraponderali, 28 (43,79%) obezitate gradul I, 11 (17,18%) obezitate gradul II, 3 (4,68%) obezitate gradul III, procentul total de pacienți obezi fiind de 65,6% (fig. 2).

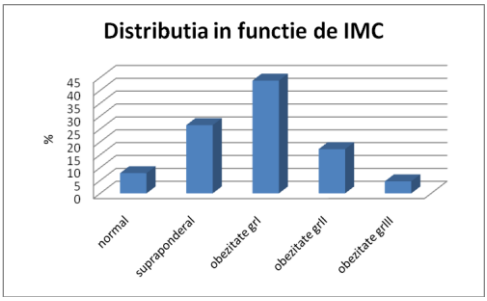

Fig. 2. Distribuția procentuală a pacienților în funcție de IMC

Din cei 64 pacienți introduşi în studiu 58 (90,60%) au fost diagnosticați cu HTA, dintre care 16 (27,5%) cu HTA gradul I, 21

(36,2%) cu HTA gradul II şi 21 (36,2%) cu HTA gradul III. Nu s-a constatat o diferență semnificativă statistic între loturi. Important de menționat este procentul de 45,3% (29) pacienți cu valori ale tensiunii arteriale diastolice (TAD) peste 90 mmHg (fig. 3,4).

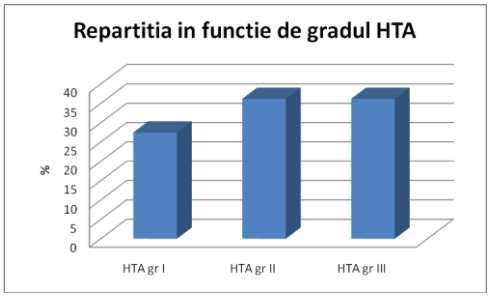

Fig. 3. Repartiția pacienților în funcție de gradul HTA

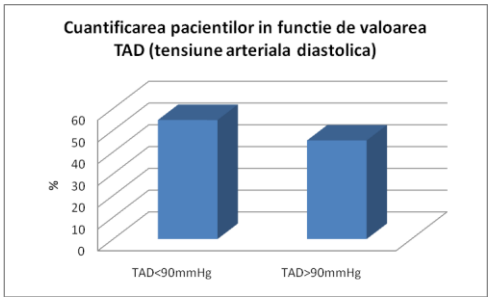

Fig. 4. Cuantificarea pacienților cu valori ale TAD>90mmHg

Pe lotul studiat ne-am propus şi cuantificarea pacienților cu frecvență cardiacă peste 70 bătăi pe minut în vederea evaluării acestui parametru ca factor de risc independent pentru bolile cardiovasculare. Nu s-a constatat o diferență statistic semnificativă între cele două loturi (fig. 5).

Au fost diagnosticați pe parcursul internării un număr de 21 (32,8%) pacienți cu diferite forme de angină pectorală. De menționat că restul de 67,2% pacienți au prezentat la externare diferite alte componente ale afectării cardiovasculare, precum HTA sau insuficiență cardiacă (fig. 6).

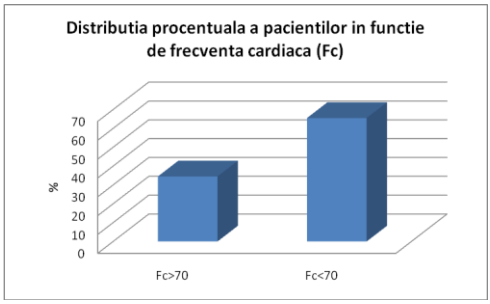

Fig. 5. Distribuția procentuală a pacienților cu FC>70 bătăi/minut

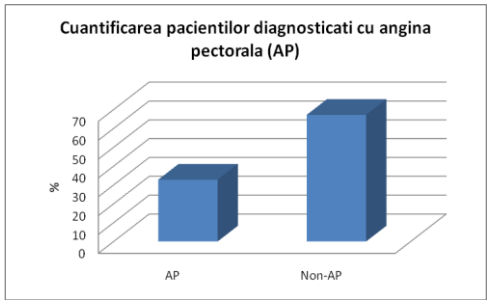

Fig. 6. Cuantificarea pacienților diagnosticați cu angină pectorală la externare

Din lotul studiat a reieşit un număr de 18 (28,12%) pacienți care prezentau scăderea toleranței la glucoză (STG) sau diabet zaharat tip 2 (DZ) (sub antidiabetice orale sau insulino-necesitant) (fig. 7).

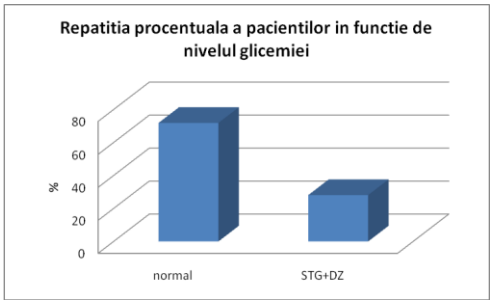

Fig. 7. Incidența modificărilor metabolice la pacienții hipotiroidieni

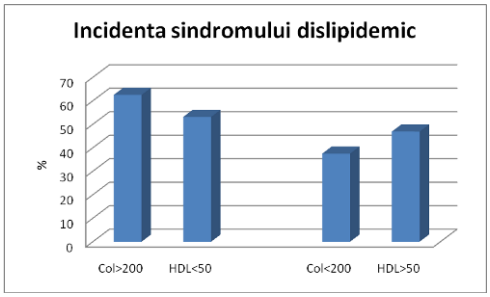

Fig. 8. Incidența sindromului dislipidemic

La lotul studiat s-a dorit şi evaluarea profilului lipidic: din cei 64 pacienți 40 (62,5%) au avut colesterolul peste 200 mg/dl, 24 (37,5%) au avut valori ale colesterolului sub 200mg/dl, 34 (53,12%) pacienți au avut valori ale HDL sub 50 mg/dl, şi respectiv 30 (46,87%) peste 50 mg/dl (fig. 8). Nu s-a constatat o diferență semnificativă între loturi.

Evaluând fracția de ejecție determinată prin ecocardiografie s-au identificat un număr de 26 (40,62%) pacienți cu fracție de ejecție sub 60% şi respectiv 38 (59,38%) pacienți cu fracție de ejecție peste 60% (fig. 9).

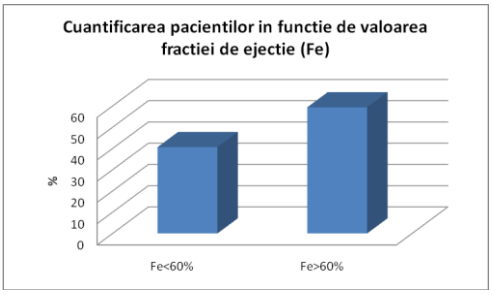

Fig. 9. Cuantificarea procentuala a pacienților în funcție de valoarea FE

DISCUȚII

Bolile cardiovasculare rămân pe primul loc între cauzele de morbiditate şi mortalitate la nivel mondial. În 2003 au fost înregistrate nu mai puțin de 16,7 milioane decese prin boli cardiovasculare (peste 29% din toate cauzele de deces) (6). Plecând de la studiile din literatură, în care se citează implicarea hipotiroidismului în determinismul bolilor cardiovasculare cu impact în special asupra funcțiilor miocardului, favorizarea patologiei coronariene şi ateroscleratice, studiul şi-a propus o cuantificare a acestor patologii raportate la cercetările deja existente, la pacienții din Clinica de Recuperare Cardiovasculară (7). În mod similar studiilor internaționale, distribuția pe grupe de vârstă (90% peste 50 ani) şi sex este concordantă (8). Chiar dacă nu există foarte multe referințe cu privire la mediul de proveniență, care la noi poate implica atât regiunea geografică (cu riscul deficitului de iod), cât şi diferențele semnificative între mediul urban şi rural (nivel de trai şi stil de viață), rezultatele sunt concordante cu datele existente (6): 72% provin din mediul urban, respectiv 28% din mediul rural. Se ştie că mediul urban, asociat hipotiroidismului, este un factor de risc cardiovascular în sine, fiind cunoscută şi dovedită importanța stilului de viață (fumat, sedentarism, stres). IMC şi circumferința abdominală aşa cum se ştie sunt markeri cu valoare predictivă pentru bolile cardiovasculare, iar procentele de 65,61% (42 pacienți) cu obezitate de diferite grade şi respectiv 92% (59 pacienți) cu circumferință abdominală peste 88 cm, indică la aceşti pacienți o asociere semnificativă şi un teren favorizant atât pentru disfuncția endotelială, cât şi pentru apariția insulinorezistenței, respectiv scăderea toleranței la glucoză şi diabet zaharat (incidență de 28,12%) (9, 10). Datele din literatură asociază în mod constant hipotiroidia disfuncției endoteliale şi scăderii disponibilului de NO (11). La acestea se adaugă rigiditatea vasculară sistemică şi rigiditatea arterială la

nivelul aortei, toate conlucrând la crearea unui teren favorizant dezvoltării HTA (12). Rezultatele pe grupul de studiu sunt concordante, cu un procent semnificativ de 90,6% (58 pacienți), cu grade variate de HTA. În acelaşi timp, de subliniat este procentul pacienților cu valori ale TAD peste 90 mmHg – 45,3% (29), care corespunde studiilor existente cu privire la acest parametru (13). Având în vedere că FC>80/min şi masa VS>270 g, se asociază cu risc crescut de ruptura de placă, la pacienții cu boală coronariană documentată, şi că o frecvență cardiacă de peste 70/min creşte cu 46% riscul de infarct miocardic la pacienții cu cardiopatie ischemică, procentul de 62,5% pacienți cu frecvență cardiacă peste 70/min este un marker important al riscului cardiovascular (14). Există dovezi că hormonii tiroidieni afectează în mod direct contractilitatea cordului, atât funcția sistolică cât şi cea diastolică, acționând prin canalele Ca-ATP-azice de la nivelul reticulului sarcoplasmatic şi de aceea a fost importantă cuantificarea pacienților cu diferite forme de angină pectorală, în studiul nostru aceştia reprezentând 32,8 % din totalul pacienților (15). Cele mai multe referințe bibliografice asociază hipotiroidiei sindromul dislipidemic şi favorizarea procesului de ateroscleroză (16, 17), chiar dacă există şi trialuri ce contrazic aceste date (18, 19). Cauza acestor modificări poate fi creşterea sintezei de colesterol în paralel cu scăderea activității LPL (lipoproteinlipazei) hepatice în contextul hipotiroidiei şi scăderea receptorilor hepatici-LDL (20). Rezultatele pe grupul nostru de studiu sunt în concordanță cu aceste date, un procent de 62,5% pacienți fiind cu valori ale colesterolului peste 200 mg/dl şi 53,12% pacienți cu valori ale HDL sub 50 mg/dl. Există o serie de studii ce asociază modificările la nivelul cordului, cu afectarea funcției sistolice şi diastolice la pacienții hipotiroidieni, şi cu uşoara scădere a FE (fracției de ejecție), ceea ce în studiu de față se regăseşte la 40,62% dintre pacienți (21).

CONCLUZII

Studiul asupra prevalenței bolilor cardiovasculare la pacienții cu hipotiroidism, internați în Clinica de Recuperare Cardiovasculară a Spitalului de Recuperare Iaşi, relevă un risc crescut de a dezvolta boli cardiovasculare şi complicații ale acestora plecând de la procentele semnificative ale markerilor relevanți atât cardiovasculari cât şi metabolici: un procent de 65,61% pacienți obezi, 28,12 % pacienți cu modificări ale profilului glucidic, 40,62% pacienți cu valori peste medie ale frecvenței cardiace.

Doi parametrii esențiali în evaluare şi cu implicații în prognosticul individual al pacienților sunt HTA şi sindromul dislipidemic. Faptul că la diagnosticare un procent de 90,62% aveau HTA de diferite grade implică necesitatea unui diagnostic mai precoce, cu prevenție primară şi secundară, şi în acelaşi timp acest parametru duce la modificarea riscului individual pe grila SCORE, de unde implicații asupra comorbidităților şi bineînțeles asupra calității vieții pacientului.

Modificarea profilului lipidic atrage după sine favorizarea procesului aterosclerotic şi riscul de evenimente cardiovasculare majore. Este deci necesară o cât mai bună evaluare a pacienților cu diagnosticul de hipotiroidie (chiar dacă şi numai subclinică), cu o cuantificare riguroasă a parametrilor clinici, inflamatori (aterosclerotici) şi ecocardiografici, permițând astfel o privire de ansamblu asupra riscului de boală cardiovasculară şi metabolică a pacientului.

SCORUL PROGNOSTIC ÎN ENDOCARDITELE INFECȚIOASE – NOU FACTOR DE PREDICTIBILITATE ÎN EVOLUȚIA BOLII

M. E. Hurmuzache [1,2]

1. Doctorand al Universității de Medicină şi Farmacie „Grigore T. Popa" - Iaşi
Universitea de Medicină şi Farmacie „Grigore T. Popa" - Iaşi
Facultatea de Medicină
2. Disciplina Boli Infecțioase

PROGNOSTIC SCORE IN INFECTIVE ENDOCARDITIS – INNOVATIVE AND USEFUL PREDICTIBILITY FACTOR FOR DISEASE´S EVOLUTION (Abstract): **Aim:** Evaluate the potential of evolution in infective endocarditis (IE) according to patient´s personal parameters (biological, clinical and paraclinical), and Carmeli score, as purpose in establishing an appropiate antibiotherapy. **Material and methods:** Clinico-therapeutic observations concerning a cohort of 868 patients admitted between 1995 and 2008 in three hospital services of Iaşi. The following guide marks were included in the study: age, sex, previous state of heart, left/right sided IE, number of valves implicated, presence of major complications, health care associated IE/nosocomial IE, major associated diseases, type of microorganism implicated/negative blood cultures. According to their importance, the score varied for each between 0 and 2, resulting a global minimum of 1 and a maximum of 10. All scores obtained were correlated with mortality and Carmeli score. **Results:** Patients with score 1-4 had a mild evolution, > 4 - < 7 usual trends of evolution with mortality close to medium rate, and 7-10 severe , mortality growing at every point with 15-18%. Carmeli score 1 was associated with 1-4 new score, 2 with > 4 - < 7, and 3 with 7-10 score. Antibiotic regimens changed usually during therapy, higher succes rates being obtained in IE with isolated pathogen. **Conclusions:** As new score may vary during patient's evolution, there is an important connection (especially at the time of admission) – but not similarity – between this new factor and Carmeli score, therapy being highly related to guide proposed regimens. However, antibiotherapy in IE should be applied using a mix of these scores, as there are important interferences due to major prognostic factors proposed in the new score, often needing next level's Carmeli score related antibiotherapy. **Key words:** INFECTIVE ENDOCARDITIS, NEW SCORE, CARMELI, ANTIBIOTHERAPY, PROGNOSTIC

Definită ca infecție a suprafeței endocardice a cordului, endocardita infecțioasă (EI), rămâne, în ciuda avansului constant în ceea ce priveşte diagnosticul şi tratamentul medical şi/sau chirurgical, una dintre cele mai severe infecții cu potențial de evoluție imprevizibil, fiind grevată de o mortalitate crescută. Acest fapt se datorează, în cea mai mare măsură, complicațiilor majore cardiace/extracardiace, a imposibilității frecvente de stabilire a diagnosticului etiologic (aprox. jumătate din cazuri având hemoculturi negative), precum şi a implicării din ce în ce mai frecvente a microorganismelor cu rezistență crescută la antibiotice, adesea cu origine nosocomială (1, 2).

MATERIAL ŞI METODE

Studiul retrospectiv a inclus 868 pacienți cu EI internați între 1995 şi 2008 în trei unități spitaliceşti din municipiul Iaşi. Au fost incluşi în lot doar pacienți cu vârsta peste 15 ani, EI survenind fie izolat, fie în contextul unei infecții sistemice (două sau mai multe determinări septice). În fiecare din cazuri am stabilit – din analiza foilor de observație – un scor prognostic individual, corelat cu 9 factori (tab. I).

TABELUL I

Valoarea factorilor predictivi în noul scor din endocardita infecțioasă

Criteriu	0 puncte	0.5 puncte	1 punct	2 puncte
Vârsta	< 45 ani	> 45 ani	-	-
Sexul	Feminin	Masculin	-	-
Îngrijiri medicale anterioare	Nu	Extraspitaliceşti (tratament la domiciliu, sonde urinare permanente, tratament stomatologic, etc)	Nosocomiale (cateterism venos/urinar, IOT, bronhoscopii, intervenții chirurgicale laborioase)	-
Comorbidități importante	Nu	Utilizatori droguri intravenoase, corticoterapie prelungită	Neoplazii, diabet zaharat, dializați cronic, ciroză hepatică, colagenoze, SIDA, TBC	-
Complicații majore	Nu	-	-	Tromboembolism, ruptură, anevrisme micotice cu metastazarea principalelor organe, abcese perivalvulare, perforări/distrugeri valvulare, insuficiență cardiacă, etc
Starea anterioară a cordului	Indemn	Extraendocardice uşoare/moderate	-	Endocardice şi extraendocardice severe -insuficiență cardiacă cronică, dispozitive antiaritmice, MCC
Preponderență	-	Cord drept	Cord stâng	-
Număr valve afectate	-	1	2 sau mai multe	-
Microorganism implicat	Streptococi cu excepțiaVREF, MSSA, staf. coagulazo-negativi, HACEK, BGN, Mycobacterium, Chlamydii, Mycoplasma	MRSA, VREF, BGN producători de betalactamaze cu spectru extins, fungi, Coxiella	Hemoculturi negative	-

Fiecare caz a fost, de asemenea, încadrat şi în scorul Carmeli (cit. 3) (tab. II).

S-au corelat cele două scoruri între ele şi cu antibioterapia propusă prin scorul Carmeli încercând a se stabili legătura între acestea şi evoluția ulterioară a pacientului, având ca principal reper rata mortalității (tab. III).

TABELUL II

Scorul Carmeli (valoarea cea mai mare indiferent de parametru)

Contact cu sistemul de îngrijiri de sănătate	Fără	1
	Fără proceduri invazive	2
	Contact prelungit cu proceduri invazive	3
Terapie antibiotică anterioară	Nu	1
	Da	2
Caracteristicile pacientului	Tânăr fără comorbidități	1
	Vârstnic ± comorbidități	2
	Imunosupresie (SIDA, BPOC, neoplazie, etc)	3

TABELUL III

Scorul Carmeli şi antibioterapia (cit. 3)

Carmeli 1	Carmeli 2	Carmeli 3
⇩	⇩	⇩
Infecții comunitare	Infecții asociate îngrijirilor medicale	Infecții nosocomiale
⇩	⇩	⇩
Amoxicilină/clav, Fluoroquinolone, Cefalosporine generația II/III, Macrolide	Ertapenem, Aminoglicozide±Fluoroquinolone, Cefalosporine de generația III/IV, Betalactamine + Inhibitori de betalactamază, Ureidopeniciline, Antistafilicocice majore, Macrolide, Fluconazol/Itraconazol	Imipenem/Meropenem, Aminoglicozide, Moxifloxacin iv, Cefalosporine generația III antipseudomonas, Cefalosporine gen. IV (Cefepim, Cefpirom), Linezolid/Vancomicină, Tigeciclină,Colistin, Antifungice majore (Voriconazol, Caspofungin)

Astfel se poate aborda o terapie antibiotică de primointenție corelând cele două scoruri, folosind uneori de-escaladarea (mai ales când diagnosticul etiologic este cert, având şi o antibiogramă utilă) sau menținerea în cazul EI cu hemoculturi negative (EIHN), atât timp cât evoluția este favorabilă (4,5,6).

Modelul local (incidență de aprox. 3 cazuri la 100000 locuitori) se suprapune în

mare măsură unui model național de tranziție, fiind de tip intermediar între cele două modele clasice, cel occidental şi cel auster, diagnosticul fiind pus prin criteriile Duke modificate (7).

Din cei 868 pacienți, 597 (68.7%) au fost bărbați şi 271 femei (31.3%), cu un raport mediu de 2.2:1 în favoarea sexului masculin. Ca şi vârstă, 2.5% aveau 15-20 ani, 14.5% 20-35 ani, 23% 35-49 ani, 35% 50-65 ani şi 25% > 65 ani, media în lotul studiat fiind de aproximativ 51 ani (peste media națională).

Factori locali predispozanți: valvulopatii reumatismale (26.8%), proteze valvulare (15.3%), dispozitive antiaritmice (2.8%), MCC (1.7%).

Factori generali: cateterism venos (15.1%), cistoscopii, sondaj vezical, chirurgie prostatică (14.3%), endoscopii digestive (12.4%), bronhoscopii, IOT (8,4%), extracții dentare, chirurgie oromaxilofacială (9.6%) şi altele sub 10% fiecare, intervenții chirurgicale digestive/obstetricale, neoplazii, diabet zaharat, hemodializă cronică, ciroză hepatică, SIDA, corticoterapie prelungită, etc.

REZULTATE

În ceea ce priveşte afectarea valvulară şi profilul etiologic, s-au obținut următoarele rezultate (tab. IV, tab. V):

TABEL IV

Afectarea endocardică

Cord stâng 67.2%	Mitrală	37.1%
	Aortică	30.1%
Cord drept 15.9%	Tricuspidă	14.7%
	Pulmonară	1.2%
Mixtă	Mitroaortică	12.1%
Extravalvulară	-	3.7%

TABELUL V

Profilul etiologic al endocarditelor infecțioase

Staphylococcus aureus	53.6% din EIHP
Stafilococ coagulazo-negativ	5.3% din EIHP
Streptococi (exceptând enterococi)	9.8% din EIHP
Enterococcus spp	18.9% din EIHP
BGN	4.8% din EIHP
HACEK	2.1% din EIHP
Fungi	3.04% din EIHP
Altele	2.46% din EIHP
Etiologii mixte	2.75% din EIHP
Hemoculturi negative	45.9% din total

Etiologie: EI cu hemoculturi pozitive (EIHP) s-a regăsit în 470 de cazuri (54.1%), cel mai frecvent implicat fiind stafilococul (277 tulpini, 123 fiind meticilino-rezistente: 44.4%), hemoculturi negative (EIHN) fiind regăsite în 45.9% din cazuri.

S-au înregistrat 224 de decese (25.8%), peste valoarea medie din modelul occidental (~ 14-15%), în special la cei cu vârste > 50 ani (tab. VI, VII).

TABELUL VI

Corelația scor Carmeli – mortalitate

	Număr cazuri	Mortalitate
Carmeli 1	437	11.2% (49 cazuri)
Carmeli 2	293	29.3% (86 cazuri)
Carmeli 3	138	65.9% (91 cazuri)

TABELUL VII

Corelația noului scor propus cu mortalitatea

Scor inițial	Număr cazuri	Mortalitate
1-1.5	48	6.25% (3 cazuri)
2-2.5	96	10.4% (10 cazuri)
3-3.5	112	13.4% (15 cazuri)
4-4.5	140	17.1% (24 cazuri)
5-5.5	168	25% (42 cazuri)
6-6.5	161	32.3% (52 cazuri)
7-7.5	96	44.8% (43 cazuri
8-8.5	31	67.7% (21 cazuri)
9-9.5	11	81.8% (9 cazuri)
10	5	100%
Total	868	224

DISCUȚII

Schemele antibiotice folosite, mai ales în ultimii ani ai studiului, au corespuns în destul de mare măsură recomandărilor din scorul Carmeli însă numărul lor a fost extrem de variat, mai adesea în asociere (două antibiotice în 596 cazuri, trei antibiotice în 219 cazuri, antibiotic+antifungic 198 cazuri).

Monoterapia a fost o excepție (53 cazuri), mai ales în primii ani de studiu. S-a semnalat tendința schimbării cel puțin a unei scheme antibiotice pe parcurs (datorită fie izolării unui agent patogen, fie evoluției nefavorabile în cazul EIHN, adeseori şi datorită „plierii" clinicienilor pe mijloacele terapeutice avute la un moment dat la dispoziție), rezultând un adevărat "cocktail" de asocieri şi replieri (8,9).

Exista o corelație bună între scorul Carmeli şi noul scor (tab. VIII).

TABELUL VIII

Corelația scor nou-Carmeli-mortalitate

Scor Carmeli			Scor nou		
	Număr cazuri	Mortalitate		Număr cazuri	Mortalitate
1	437	11.2%	1-4	396	14.3%
2	293	29.3%	>4-<7	329	28.1%
3	138	65.9%	7-10	143	58.3%

Scorul nou este adaptabil pe toată perioada internării, unii factori predictivi, putând fi introduşi / modelați pe parcurs. În absența cunoaşterii agentului etiologic, toate cazurile au fost interpretate drept EIHN (1 punct).

Corelarea celor două scoruri cu antibioterapia s-a făcut într-un mod mai elastic, existând perioade foarte diferite în studiu, în ceea ce priveşte posibilitățile terapeutice şi modul de abordare a antibioterapiei (10,11). În cazul EIHN, dificilă de tratat, în ciuda multiplelor asocieri antibiotice/antifungice, abordarea se poate simplifica (tab. IX).

TABELUL IX

Tratamentul endocarditelor infecțioase cu hemoculturi negative

Proteză valvulară	**Durata (săptămâni)**
Vancomicină	Minim 4
+Aminoglicozid	2-4
+Rifampicină ± fluoroquinolonă (debut tardiv > 1 an	Minim 4
SAU	
Penicilină M/Cefalosporine gen III/IV	4-6
+ Aminoglicozid	2-4
+Rifampicină (suspiciune MSSA)	4-6
Valvă nativă	
Aminopenicilină+sulbactam	Minim 4
+aminoglicozid	2-4
SAU	
Vancomicină	4-6
+aminoglicozid	2-4
+fluoroquinolonă	4-6
EI nosocomială	
Cefalosporină gen III/IV+vancomicină +aminoglicozid	4
Purtător pacemaker	
Vancomicină+fluoroquinolonă	4-6

Antibioterapia trebuie stabilită cu prioritate funcție de scorul nou, fără a ne cantona întotdeauna în recomandările scorului Carmeli, existând posibilitatea abordării antibiotice de nivel superior Carmeli-asociată, funcție de o serie de particularități ale unor pacienți.

Mortalitatea este mult crescută în cazul stafilococilor meticilino-rezistenți, cu afectare a cordului stâng, protezaților valvular sau cei cu afecțiuni cardiace majore în antecedente. În ordine descrescătoare, în cazul EIHP, mortalitatea se întâlneşte în cazul MRSA, fungilor (12) şi a enterococilor rezistenți. Regimurile terapeutice antimicrobiene au avut o bună bucată de timp o orientare oarecum „caracteristică" fiecărei clinici în parte, existând o mare diversitate de opțiuni. În ultimii ani se poate remarca o remodelare a abordării terapeutice pe principii mult mai obiective, cu o colaborare interdisciplinară mai strânsă, rezultatele neîntârziind astfel să apară.

CONCLUZII

Cercetarea lotului de 868 de cazuri de EI, reliefează faptul că scorul Carmeli nu era perfect adaptat acestei infecții severe, fapt ce m-a determinat să extind plaja factorilor prognostici şi să îi corelez cu terapia antibiotică şi cu mortalitatea. Ca atare, o evaluare rapidă a pacienților încă de la

internare – dar şi pe parcurs – conform noului scor, a ajutat, împreună cu recomandările antibiotice din scorul Carmeli, aprecierea posibilităţilor evolutive cât şi abordarea terapeutică. Stabilirea noului scor, care nu a necesitat mijloace deosebite, ci doar o anamneză şi un diagnostic riguros, a reprezentat un reper important în monitorizarea acestei infecţii cu potenţial foarte sever.

RESTRICTIVE FILLING PATTERN-A MAJOR NEGATIVE PROGNOSIS FACTOR IN DILATED CARDIOMYOPATHY (Abstract): Dilated cardiomyopathy (DCM) represents an important cause of chronic heart failure and, thereby, of morbi-mortality worldwide, not only because of its high-risk for sudden death, but also by its evolutive complications (arrhythmias, thromboembolic accidents). The objectives of the study: selection of patients with DCM in sinus rhythm and with a restrictive pattern at echo-Doppler examination, analysis of relevant epidemiological, clinical and echocardiographic parameters and their correlation with a negative prognosis. **Material and methods**: Retrospective evaluation of a total of 300 patients admitted to the Cardiology Clinic of "Sf. Spiridon" Hospital between January 2017 and December 2017 with the confirmed diagnosis of DCM. Of these, applying the exclusion criteria, we selected 120 patients for further evaluation. **Results**: Of the analyzed patients, 85 were men and 35 were women, the proportion of those > 60 years old being 71.66%, while those <60 years representing 28.34% of the total, the mean age being 64.4 years. Male sex was significantly correlated with ischemic ($p = 0.000001$) and ethanolic ($p = 0.05$) etiology of DCM, as well as with a more severe symptomatology (NYHA III-IV, $p = 0.007$) compared to women. The restrictive pattern was echocardiographically detected in 79 patients (65.83% of cases) and showed a statistically significant association with the male sex ($p = 0.03$), the older age ($p = 0.00006$), but also with an ejection fraction <25% ($p = 0.007$) or with the presence of the left bundle branch block ($p = 0.05$). All patients with unfavorable evolution (7.5%) or who died later (4.15%) showed a restrictive pattern, showing a clear link between its presence and a poor prognosis. **Conclusions**: The present study reveals the major negative influence of the restrictive pattern on the prognosis and subsequent evolution of DCM patients, as well as its interdependence with other clinical and epidemiological parameters. **Keywords:** DILATATIVE CARDIOMYOPATHY, RESTRICTIVE PATTERN, POOR PROGNOSIS.

Dilated cardiomyopathy (DCM) represents an important cause of chronic heart failure and, thereby, of morbi-mortality worldwide, not only because of its high-risk for sudden death, but also by its evolutive complications, which may range from severe rhythm disorders (atrial fibrillation, ventricular tachycardia) to thromboembolic accidents.

Several factors that could influence the

progression and prognosis of patients with DCM have been studied, recalling systolic dysfunction (FEVS <45%), old age, NYHA III-IV grades of heart failure, arrhythmias and diastolic left ventricular dysfunction (1, 2).

Regarding the importance of diastolic dysfunction as a prognosis factor, these stems from the fact that most patients with DCM present at the echocardiographic examination a certain degree of alteration of the diastolic function, the most important severity being associated with the restrictive type, which also has the most reserved long-term prognosis (3).

The objective of our study was to identify patients with DCM in sinus rhythm, to assess certain relevant echocardiographically, clinical and epidemiological parameters in pathological context, to select those patients who had a restrictive pattern in the eco-Doppler examination and to correlate the presence of this pattern with subsequent progression and prognosis of the patients.

MATERIAL AND METHODS

Our study retrospectively evaluated a total of 300 patients admitted to the Cardiology Clinic of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi between January 2017 and December 2017 with the confirmed diagnosis of DCM. Of these, we selected for subsequent evaluation a total of 120 patients with sinus rhythm, the absence of which was an exclusion criterion. Patient noncompliance, their refusal to be echocardiographically examined or the low-quality echographic window were other exclusion criteria. The DCM diagnosis was primarily based on echocardiographic appearance and data (dimensions, volumes- the evidence of cavity enlargement, other suggestive parameters for systolic and / or diastolic dysfunction) supported by other clinical data (signs and symptoms of left or global heart failure, mitral valve insufficiency, third heart sound-gallop etc.) and electrocardiographic changes (indirectly by signs of left ventricular hypertrophy). In addition, biological determinations (hem leucogram → macrocytosis, electrolytes, renal function) were performed. Anamnesis was useful in some situations to objectify the etiologies (ethanolic, viral, ischemic, cardiotoxic medication). For the determinations, we used the Samsung Ugeo H60 echocardiograph, with the Doppler pulsed-wave function cursor placed on the tip of the mitral valve. A restrictive pattern was considered if E / A> 2, with DTE <140 ms and IVRT <60 ms. Patients signed and agreed on admission to participate in the research process, their data being processed anonymously. All data was statistically analyzed using the *Microsoft Excel* 2010 and *Epi Info 7* software and for p-value we used the two-tailed test.

RESULTS

From the point of view of epidemiological aspects, out of a total of 120 patients analyzed, 85 (70.83%) were men, while women were 35 (29.17%).

For the comparative analysis by age groups, we divided the patients into two groups: those aged more than or equal to 60 years (86 cases, 71.66%), respectively patients under 60 years (34 cases, 28.34%), mean age being 64.4 years.

Following the echocardiographic evaluation, the restrictive pattern was detected in 79 patients (65.83% of cases), while an ejection fraction (EF) of less than 25% was observed in only 20 patients (16.66%).

In terms of evolution, 111 (92.5%) showed a favorable evolution at 3 months, compared to the remaining 9 patients (7.5%) who had a severe evolutionary path, of these remaining cases, 5 being followed by death (4.16%) (Fig.1).

We noticed that the clinical manifestations of heart failure correlate with age, the share of patients in NYHA III-IV classes being significantly more important in the age group> 60 years (64.1% versus 20.9%, p = 0.027). Also, regarding DCM etiologies, although we have noticed certain percentage differences when assessing the age groups, they have failed to reach the statistical significance threshold (tab. I).

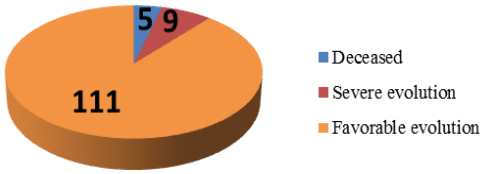

Fig. 1. Evolution of the patients

TABLE I

Severity of symptoms and etiology of DCM related to age

	>60 years No=86 (%)	<60 years No=34 (%)	Total No=120 (%)	p
NYHA III-IV	77 (64.1%)	25 (20.9%)	102 (85%)	0.027
Ischemic DCM	15 (12.5%)	11 (9.2%)	26 (21.7%)	0.075
Mixed DCM	18 (15%)	6 (5%)	24 (20%)	0.68
Ethanolic DCM	37 (30.8%)	15 (12.5%)	52 (43.3%)	0.91
Valvular DCM	13 (10.8%)	5 (4.2%)	18 (15%)	0.95

Analyzing the same parameters but focusing on the influence of the patients' sex, we revealed the direct correlation between male sex and the presence of ischemic etiology (p = 0.05), respectively the ethanolic DCM (p = 0.000001), these statistically significant values confirming the higher incidence of ischemic events in men and, also, certain social behaviors (chronic ethylism). The same trend can be observed for the symptoms of heart failure, the proportion of male patients in NYHA III-IV classes being significantly higher than that of women (90.6% of men vs. 71.4% of women, p = 0.007). Unlike the previous aspects, no statistically significant differences regarding sex of the patients were observed for valvular and mixed etiology of DCM (tab. II).

TABLE II

Severity of symptoms and etiology of DCM related to sex

	Men No=85 (%)	Women No=35 (%)	Total No=120 (%)	p
NYHA III-IV	77 (64.1%)	25 (20.9%)	102 (85%)	0.007
Ischemic DCM	23 (19.1%)	4 (3.3%)	27 (22.4%)	0.05
Mixed DCM	17 (14.15%)	7 (5.85%)	24 (20%)	0.95
Ethanolic DCM	47 (39.1%)	4 (3.3%)	51 (42.4%)	0.000001
Valvular DCM	12 (10%)	6 (5%)	18 (15%)	0.67

Of the 79 patients with restrictive pattern, premature ventricular contractions (PVC) on ECG were identified in 31 cases (25.83% of total patients, p = 0.03), while

the left bundle branch block (LBBB) was present in 19 cases (15.83%, p = 0.05), this data revealing the statistically significant correlation between the presence of arrhythmias and severe diastolic dysfunction in patients with DCM (tab. III).

TABLE III

Correlation between ECG anomalies and restrictive pattern

	With restrictive pattern No=79 (%)	Without restrictive pattern No=41 (%)	Total No=120 (%)	p
With PVC	31 (25.83%)	8 (6.66%)	39 (32.5%)	0.03
With LBBB	19 (15.83%)	4 (3.33%)	23 (19.16%)	0.05

The proportion of male patients with restrictive pattern was significantly higher than that of women (61 *vs.* 18, p = 0.03), objectifying a cumulative effect of negative prognosis factors in these patients. Also, the elderly patients were correlated with an increased frequency of restrictive type diastolic dysfunction, out of a total of 86 patients > 60 years of age, 66 presenting this pattern (p = 0.00006) (tab. IV).

TABLE IV

Association between restrictive pattern and some epidemiological data

	With restrictive pattern No=79 (%)	Without restrictive pattern No=41 (%)	Total No=120 (%)	p
Men	61 (50.83%)	24 (20%)	85 (70.83%)	0.03
Women	18 (15%)	17 (14.15%)	35 (29.15%)	
Age>60 years	66 (55%)	20 (16.66%)	86 (71.66%)	0.00006

In patients with a restrictive pattern in the echocardiographic analysis, we noticed a statistically significant correlation between the presence of this diastolic dysfunction and an EF lower than 25% (p = 0.007), thus evidencing the presence of a severe double dysfunction, systole-diastolic, in patients with DCM. Also, the restrictive pattern correlated with an unfavorable prognosis, basically all patients with severe evolution (7.5%) or deceased (4.15%), presenting the echocardiographic characteristics of this type of diastolic dysfunction (tab. V). The presence of spontaneous echo-contrast in LV, a marker of severity, should be noted, its presence being found predominantly in cases with restrictive pattern (9 *vs.* 1, p = 0.09).

TABLE V

The influence of restrictive pattern on some echocardiographic findings and the evolution of the patients

	With restrictive pattern No=79 (%)	Without restrictive pattern No=41 (%)	Total No=120 (%)	p
EF<25%	17 (14.15%)	3 (2.5%)	20 (16.65%)	0.047
Spontaneous LV echo-contrast	9 (7.5%)	1 (0.85%)	10 (8.35%)	0.09
Severe evolution	9 (7.5%)	0	9 (7.5%)	0.02
Death	5 (4.15%)	0	5 (4.15%)	0.09

DISCUSSION

Although literature data is limited in terms of the actual prevalence of restrictive diastolic dysfunction in DCM patients, some studies have identified some epidemiological trends. Thus, both in our study and in the research carried out by Pinamonti and Mehani, there is a net predominance of male DCM patients with restrictive pattern (3, 4), an explanatory aspect being the overall prevalence of DCM among men.

Several previous studies have highlighted the role of systolic dysfunction as a negative prognosis factor in patients with DCM (9, 10). In our study, we identified 20 patients with a severely diminished ejection fraction, significantly correlated with the presence of the restrictive type pattern and thus with a reserved prognosis. A Rihal study on a group of >100 DCM patients revealed the negative prognosis role of an EF <25% in patients with DCM and diastolic dysfunction (5), due to the interdependence between LV stiffness, high filling pressures and volume-pressure curve modification. Janicki also demonstrated that when all four cavities are dilated, parietal rigidity is also influenced by the pericardial restriction, as a result globally affecting the systolic-diastolic function (6).

As for CMD etiology, most of the data in the literature plead for the association between ischemic origin and male gender, this fact being confirmed by the data from our study ($p = 0.05$). However, considering that the analyzed population originates from the NE region of Romania, two researches made by Costache *et al.* must be mentioned regarding the prevalence of cardiovascular risk factors in the two sexes, highlighting a predominance of coronary ischemia in women, which represents an important risk factor for the further development of DCM (7, 8).

Although the association between DCM and arrhythmias was confirmed by multiple evidence from literature, relatively few studies highlighted their influence on patient prognosis. In the present paper we underlined the statistically significant association between the restrictive filling pattern and the arrhythmias (premature ventricular contraction-> $p = 0.03$ or left bundle branch block (LBBB)-> $p = 0.05$), but we could not quantify their influence on the subsequent evolution. However, one study from 2014 indicates that LBBB *"per se"* negatively influences the long-term prognosis, especially as it is established after initiation of therapy with inhibitors of the conversion enzyme (14). Moreover, Costache *et al.* also demonstrated a clear association between LBBB and an infaust prognosis in patients with DCM ($p < 0.0001$) (13). In addition, considering that all DCM patients had enlarged LV, with diameters >55 mm, it is important to mention that Aleong *et al.* demonstrated the superior predictive value of LV diameter compared to diminished EF in prediction of ventricular arrhythmias, thereby being a marker for a reserved prognosis in DCM patients (16).

The restrictive pattern was associated with a negative prognosis not only in the present study but also in the studies of Shen and Pinamonti on cohorts of patients with DCM, mortality being recorded only in the groups presenting this type of filling ($p < 0.0001$). One-year survival rates were similar between our study and those of Pinamonti (95.83% *vs.* 89%), a significantly higher mortality being seen in Shen's research (survival rate of 60.3%), with the indication that the follow-up period and the

final balance respectively in the latter case was 31±12 months (3, 11).

Similar data regarding the future evolution of patients with restrictive pattern were obtained by Klein and Costache in patients with amyloidosis, confirming that restrictive-type diastolic dysfunction is a global negative prognostic factor in multiple cardiac pathologies (12, 15).

CONCLUSIONS

In conclusion, the present study reveals the major influence of the restrictive pattern on the prognosis and subsequent evolution of DCM patients, as well as its interdependence with other clinical and epidemiological parameters. Thus, the restrictive type was significantly correlated with the presence of other negative prognosis factors (systolic dysfunction, male gender, advanced age), defining a complex set of risk factors that further influence the morbidity of DCM patients. Subsequent multiannual researches with a significantly increased number of patients are needed to highlight the dynamical evolution of diastolic dysfunction as a poor prognosis factor in DCM patients and for a better risk stratification in patients at risk of sudden death or candidates for a cardiac transplantation.

ENVIRONMENTAL POLLUTANTS AND PREMATURE OVARIAN INSUFFICIENCY

Until now several etiological factors were described for premature ovarian failure, but not the impact of environment on this pathology which is the aim of this review. Environmental pollutants (pesticide, phenol or bisphenol, flame retardant, dioxin, cosmetic, xenobiotic, cigarettes smoke) can be deleterious to women health especially altering the reproductive function and steroidogenesis with the impact on ovarian function by three ways: endocrine disrupting chemicals; induction of oxidative stress an epigenetic modification. These ways can coexist and influence the ovarian reserve by increasing follicular atresia; increasing activation of primordial follicles; by blocking of folliculogenesis before the antral stages or by decreasing of the pool of resting primordial follicles. Moreover, some pollutants such as phthalates have a transgenerational effect by the effect on DNA methylation of imprinted genes. This review reinforces the notion that the environmental pollutants act as endocrine disruptors with a key role in the induction of POI. The severity of the syndrome depends on dose and window of exposure. Exposure to environmental pollutants is a critical public health problem that need an information of patients about the risk of POI with the possibility to prevent the consequences of this syndrome by preserving fertility (Pauline Vabre, Nicolas Gatimel, Jessika Moreau, Veronique Gayrard, Nicole Picard-Hagen, Jean Parinaud and Roger D. Leandri. Environmental pollutants, as a possible etiology for premature ovarian insufficiency: a narrative review of animal and human data. *Environmental Health* (2017): 16-37).

3. Disciplina de Boli Infecţioase

DEMOGRAPHIC, CLINICAL AND LABORATORY CHARACTERISTICS OF ERISYPELAS IN THE PERIOD 2001-2010 (Abstract): **Aim**: to describe demographic and clinical characteristics of erysipelas and to compare the sensitivity of two laboratory tests. **Material and methods:** we studied patients with erysipelas hospitalized in the Dermatological Clinic between 2001 and 2010. **Results:** the investigated 140 cases represented 8% of all skin infections hospitalized. Distribution of annual admissions has shown a gradual reduction in the number of admissions in the second half of the decade. A higher frequency was found in the second half of the year. Most patients were from rural areas (55%). The female gender predominated (69.3%).With few exceptions, the patients were adults averaging 59 years. The most common location was the lower leg (91.4%). Most clinical forms were mild and medium. Septic complications were absent. Recurrent erysipelas occurred in 5% of cases. Comorbidity included: chronic venous insufficiency (14.2%), hypertension (10%), obesity (8%), diabetes mellitus (5.7%) or chronic hepatitis (3.5%). **Conclusions:** the "benign" appearance of our cases is contrary to the trend rate of severe cases of cutaneous streptococcal infections in some western areas. From comparing laboratory tests results we observed their frequent mismatch. The ESR and the increase in percentage of polymorphonuclear neutrophils were more significant than the total number of leukocytes. Etiological therapy with penicillin G at a dose of 4 million UI/day was effective. The analysis allows the establishment of demographic and clinical features of erysipelas during the period and given territory.
Key words: SKIN, INFECTION, STREPTOCOCCUS

Infecţiile cutanate bacteriene sunt răspândite pe tot globul. Afectează toate vârstele. Pot fi primare sau secundare, superficiale sau profunde. Agenţii etiologici cel mai frecvent implicaţi sunt *Staphylococcus aureus* şi *Streptococcus pyogenes*. Mai rar sunt cauzate de alte bacterii Gram pozitive sau Gram negative, aerobe sau anaerobe.

Obiectivul lucrării a constat în cunoaşterea caracteristicilor demografice, clinice şi a unor aspecte paraclinice ale erizipelului într-un teritoriu din Estul României în perioada 2001-2010, dată fiind posibilitatea variaţiei acestor parametrii în raport cu spaţiul şi timpul de evoluţie. Totodată neam propus compararea sensibilităţii testelor paraclinice (hemoleucograma şi viteza de sedimentare a hematiilor) în aprecierea intensităţii procesului inflamator.

MATERIAL ŞI METODE

Am realizat un studiu retrospectiv (pentru perioada 2001-2003) şi prospectiv (2004-2010) ce a urmărit pacienţii diagnosticaţi cu erizipel în Clinica Dermatologică Iaşi.

S-au evaluat caracteristicile demografice, clinice (aspect, localizare, evoluţie) şi semnificaţia unor date paraclinice (hemoleucograma şi VSH) pentru aprecierea intensităţii procesului inflamator şi utilitatea lor în diagnosticul afecţiunii.

Analiza statistică a folosit programe computerizate specializate (Microsoft Excel, Analyse-It) pentru calcularea de valori medii, mediane, intervale de încredere 95%, testul *χ2, t-Student*. Un $p<0,05$ a fost considerat semnificativ.

REZULTATE

În perioada studiată, infecţiile cutanate bacteriene diagnosticate la 1120 de pacienţi au constituit 6,19% din totalul de 18083 internaţi. În 30% din infecţiile cutanate au fost incriminate streptococul, erizipelul fiind cea mai frecventă afecţiune, totalizând 41,6% din cazuri (140 din 336)(tab. I).

TABELUL I

Distribuţia anuală a cazurilor de piodermită streptococică

Forma clinică	2001	2002	2003	2004	2005	2006	2007	2008	2009	2010	Total
Erizipel	25	19	20	9	15	7	12	11	13	9	**140**
Impetigo	14	15	18	20	13	15	9	7	6	7	**124**
Intertrigo	2	4	1	-	1	6	2	4	5	3	**28**
Ectimă	-	5	6	5	2	2	3	1	-	2	**26**
Streptococia scalpului	2	-	1	-	3	-	-	2	1	-	**9**
Pitiriazis alb al feţei	2	2	3	-	1	-	1	-	-	-	**9**
Total	**45**	**45**	**49**	**34**	**35**	**30**	**27**	**25**	**25**	**21**	**336**

Variaţia numerică anuală a internărilor pentru erizipel se situează între 11 şi 25 de cazuri cu excepţia anilor 2004 şi 2006 când s-au internat doar 9 respectiv 7 bolnavi cu această afecţiune. Numărul mediu anual de cazuri a fost de 14 (95%CI 9.9 - 18.1).

În ceea ce priveşte repartiţia lunară a internărilor rezultă preponderenţa acestora în lunile VI-XII: 62,1% din cazuri.

Cu câteva excepţii, toţi pacienţii au fost adulţi (tab. II). Vârsta medie a pacienţilor a fost de 59 ani (54 ani pentru bărbaţi, 60 pentru femei). Majoritatea pacienţilor (79,2%) au depăşit vârsta de 50 de ani.

Mediul de proveniență al bolnavilor a fost în 55 % din cazuri rural şi 69,3% au fost de sex feminin (tab. III).

Localizarea cea mai frecventă a placardului eritemato-edematos a fost la nivelul gambelor (91,4%) şi la 8.6% acesta s-a situat la coapsă, picior, faţă, sân.

Formele clinice apreciate în raport cu simptomele generale şi locale, au fost uşoare şi medii.

Feminin	60	Obezitate	11 (8)
Sexul		Diabet	8 (5,7)
Masculin	43 (30,7%)	Hepatită cronică	5 (3,5)
Feminin	97 (69,3%)	Etilism	2 (1,4)
Mediul de proveniență		Neoplazii	1 (0,7)
Urban	77 (45%)	TBC	1 (0,7)
Rural	63 (55%)	Ulcer gastro-duodenal	1 (0,7)
Localizarea infecției	**%**	**Forme clinice**	**%**
Gambe	91.4	Uşoare	30
Alte localizări (coapsă, picior, față, sân)	8.6	Medii	70
Erizipel recidivant	5	Letalitatea	0

Erizipelul recidivant s-a înregistrat la 5% din cazuri. Într-un singur caz s-au constatat 2 recidive, primul erizipel în 2002, al doilea după un an şi al treilea după alte 4 luni.

Comorbiditățile constatate au fost: insuficiența venoasă cronică (14,2%), hipertensiunea arterială (10%), obezitatea (8%), diabetul zaharat tip II (5,7%) şi hepatita cronică (3,5%)(tab. III).

Valorile scăzute ale VSH la 2 ore (între 15-29 mm) s-au înregistrat la 10,5% din cazuri, 39% au avut între 30-50 mm, 27,5%, 60-90 mm iar 23%, 100-150 mm. În 50,5% din cazuri valorile VSH-ului au fost de 60-150 mm (tab.IV). Valorile crescute ale VSH-ului au fost, în 29% din cazuri, concordante cu hiperleucocitoza şi procentul crescut al polimorfonuclearelor neutrofile.

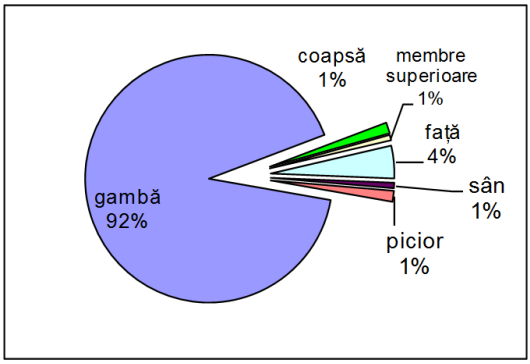

Fig. 1. Repartiția pacienților în relație cu localizarea infecției

TABELUL IV

Relația VSH-leucogramă la 57 bolnavi cu erizipel

	VSH/2h (mm)				Total
	<30	30-50	60-90	100-150	
LN PN	5	12	10	2	33
LN PC	1	3	1	1	10
LC PN	2	1	2	3	8
LC PC	2	-	2	2	6
Total	10(17.5%)	16(28%)	15(26.3%)	16 (28%)	57

LN- nr. normal leucocite, LC-nr. crescut leucocite
PN - nr. normal de polimorfonuclearеneutrofile PC- nr. crescut de polimorfonuclearеneutrofile

Terapia etiologică a erizipelului variază atât în ceea ce priveşte antibioticul folosit, dozaj, calea de administrare şi durată.

Cel mai frecvent folosite sunt betalactaminele, pe primul loc situându-se penicilina G şi V (tab. V).

TABELUL V

Antibiotice folosite în terapia erizipelului

Antibiotic	Nr. Pacienți	%
Penicilina G		
7 zile	54	38.5
10 zile	15	10.7
7 zile + Moldamin	40	28.6
Oxacilină	4	2.8
Amoxicilină	10	7.1
Ciprofloxacină	11	7.6
Eritromicină	2	1.4
Unasyn	2	1.4
Ceftriaxonă	2	1.4

În cazuistica noastră 77% din bolnavi au primit penicilina G în doză zilnică de 4 milioane UI administrată intra muscular în 4 prize; 67 % timp de 7 zile, iar pentru 10,7 % a fost de 10 zile; majoritatea dintre aceştia primind benzantin penicilina (Moldamin 1200000 U) după 7 zile de penicilina G.

Aminoglicozidele (Amoxil şi Unasyn) au fost folosite în 8,56% din cazuri, fiind utilizate în multe țări datorită căii orale de administrare şi a bio-disponibilității ridicate.

DISCUȚII

Erizipelul, în perioada studiată (2001-2010), a fost cea mai frecventă infecție bacteriană cutanată spitalizată în Clinica de Dermatologie din Iaşi - 140 (41,6% din total), dar a reprezentat numai 0,8% din patologia cutanată tratată.

S-a remarcat o reducerea numărului de internați în a doua parte a deceniului; în prima jumătate numărul mediu anual fiind de 17,6, iar în ultimii 5 ani de 10.4, diferența fiind semnificativă statistic (t=2,5, p=0,03). Această scădere a numărului de internări pentru erizipel s-ar putea datora unui acces mai facil al pacienților la o terapie orală cu antibiotice în ambulatoriu, îmbunătățirii măsurilor de prevenție sau de educație pentru sănătate a populației dar şi urmarea adresabilității spre alte specialități. Date ale unor cercetători belgieni (1), dintr-un studiu similar, au constatat o creştere a incidenței erizipelului în anii 2000-2004.

Au fost afectați în special persoane vârstnice – media 59 ani, o proporție semnificativă (45%) având şi alți factori favorizanți pentru grefarea unei infecții streptococice cutanate: insuficiență venoasă cronică – 14.2%; obezitate – 8%; diabet zaharat – 5.7%, ceea ce concordă cu datele din literatură (2).

Marea majoritate au avut ca localizare a erizipelului gamba şi doar 4,3% în aria facială. Această observație este în acord cu a lui Jorup-Ronstrom.(3) care a constatat reducerea frecvenței erizipelului feței.

Aspectul "benign" al cazurilor studiate nu corespunde cu datele publicate în ultimele decenii în Europa, Asia şi America de Nord (2).

Recidivele erizipelului au fost rar semnalate de noi (5%), comparativ cu cele ale altor specialişti care sunt în medie sunt de 18%. (3)

Cel de-al doilea obiectiv al studiului a fost stabilirea sensibilității testului VSH comparativ cu datele hemoleucogramei. Datele noastre sunt similare cu ale lui Concheiro (4,5) în ceea ce priveşte sensibilitatea mai mare a VSH-ului comparativ cu hemoleucograma dar diferă de ale acestuia în privința corelării valorilor testului cu intensitatea inflamației apreciată clinic, întrucât în cadrul cazurilor uşoare şi medii aceste valori au fost în mod egal reprezentate.

Doza de penicilină G folosită de noi se încadrează în recomandarea infecționiştilor şi dermatologilor români (1,6-3 milioane, Voiculescu; 2,4-4 milioane, Forsea; 1,6-4 milioane, Diaconu)(6, 7, 8). Efectul terapeutic benefic asupra evoluției fenomenului inflamator local, cât şi evitarea complicațiilor septice locale a fost constant.

Unii specialişti sugerează reducerea timpului de administrare la 5 zile iar alții consideră că prelungirea terapiei cu benzantin penicilină pentru prevenția recăderilor este neconvingătoare (3).

Folosirea eritromicinei la persoanele alergice la penicilină este limitată urmare a răspândirii tulpinilor de streptococ de grup A eritro-rezistente, situație remediată prin administrarea de cefalosporine din grupul I sau II (9).

Schemele terapeutice utilizate s-au dovedit eficiente realizând reducerea inflamației locale şi prevenind complicațiile septice.

CONCLUZII

Analiza caracterelor demografice, clinice şi paraclinice din Clinica ieşeană au permis evidențierea unor particularități ale erizipelului în primul deceniu al secolului XXI:

- în a doua perioadă a deceniului se constată o reducere anuală a internărilor, în special la vârsta copilului şi adolescentului;
- creşte în mod important localizarea infecției la membrele inferioare şi scade pentru extremitatea cefalică;
- se constată predominanța formelor medii şi uşoare;
- se confirmă utilitatea redusă a modificărilor hemoleucogramei în diagnosticul acestei afecțiuni;
- doza de penicilină G de 4 milioane de UI/zi i.m. a fost eficientă.

Studiul efectuat permite conturarea aspectului general al erizipelului într-o zonă estică a țării, în primul deceniu al secolului XXI.

CANCERUL COLORECTAL – CONSIDERAŢII ASUPRA TENDINŢELOR EVOLUTIVE ALE PROFILULUI EPIDEMIOLOGIC ŞI ANATOMOCLINIC

A. Dumitrescu [1], Gh. Bălan [2]

1. Doctorand al Universităţii de Medicină şi Farmacie "Gr. T. Popa Iaşi"
2. Institutul de Gastroenterologie şi Hepatologie Iaşi

COLORECTAL CANCER – THE EVOLUTION TENDENCIES OF THE EPIDEMIOLOGIC AND ANATOMOCLINICAL PROFILE (Abstract): In the past 3 years colorectal cancer became the second cause death (after the broncho-pulmonary cancer) exceeding gastric cancer by 4150 deaths in 2002 (19,05%ooo inhabitants) and 4860 deaths in 2006. **Material and methods:** 644 of the 18,978 patients coloscopically investigated at the Iasi Gastroenterology and Hepatology Institute in the interval 2000-2007 in which pathology results revealed colorectal cancer, and 279 patients operated at the First Clinic Surgery of the Iasi "Sf. Spiridon" Hospital during 2008-2010 were selected for this study. **Results:** Colorectal carcinoma has a high incidence in the patients over 60 years. Sex distribution of the tumors showed that this disease most commonly affects males. The male/female ratio was 1.3. In less than 3% of the cases the disease occurred at ages under 40 years. The most frequent clinical manifestations were intestinal transit disorder (97%), pain syndrome on the left side of the abdomen (82.82%), and progressive severe constipation (67.89%). 24.07% of the colorectal cancer cases were located at the level of the proximal colon (cecum, ascending colon, hepatic flexure, transverse colon and splenic flexure), while 75.9% were located at the distal level. The most frequent macroscopic form was the vegetative one (89.91%). **Key words**: CANCER, CANCER COLORECTAL, EPIDEMIOLOGY.

Patologia tumorală reprezintă o problemă majoră de sănătate publică pentru care se alocă enorme resurse materiale şi umane în vederea descifrării mecanismelor de apariţie, dezvoltare şi progresie.

Cancerul a provocat decesul a 7,6 milioane de persoane la nivel mondial în 2008, mai ales în ţările în curs de dezvoltare, potrivit unui studiu al Centrului internaţional de cercetări asupra cancerului (CIRC, organism al OMS), dat publicităţii în 2008. 56% dintre cele 12,7 milioane de noi cazuri de cancer şi 63% din totalul de 7,6 milioane de decese asociate unui cancer au survenit în ţări în curs de dezvoltare. Potrivit CIRC, mortalitatea asociată cancerului a crescut în ultimii ani în lume, cele mai frecvente forme de cancer fiind cel pulmonar, de sân, colorectal, de stomac şi de prostată.

Cancerul colorectal este ce mai frecventă tumoră malignă şi cea mai frecventă cauză de deces prin cancer în ţările industrializate din Europa (58.300 decese/an) şi Statele Unite ale Americii(156.000 cazuri noi/an) (2). În România, frecvenţa CCR este în creştere rapidă (dublarea incidenţei şi mortalităţii în ultimii 20 de ani) atingând

în anul 2000 o incidenţă de 17,74%ooo pe an, ceea ce plasează ţara noastră în rândul ţărilor cu incidenţă medie a bolii. În ultimii 3 ani, CCR a devenit a doua cauză de deces (după cancerul bronho-pulmonar, devansând cancerul gastric cu un număr de 4150 de decese în 2002 (19,05%ooo locuitori). şi 4860 decese în 2006. Circa 60% din pacienţii cu CCR se prezintă cu boală avansată, metastazele hepatice fiind cele mai frecvente (1).

Incidenţa medie a cancerului colorectal în judeţul Iaşi în perioada (2004 - 2007) a fost de 15,23 la 100.000 de locuitori. Această valoare aşează judeţul Iaşi într-o zonă de incidenţă medie în raport celelalte zone ale ţării.

Mortalitatea medie în aceasta perioadă a fost de 12,5 ‰ în judeţul Iaşi faţă de 18,25 ‰ în ţară (3).

MATERIAL ŞI METODE

Pentru studiul tendinţelor evolutive ale profilului epidemiologic şi anatomoclinic al cancerului colorectal în studiu s-a avut în vedere perioada 2000 – 2007 interval în care au fost investigaţi colonoscopic în cadrul Institutului de Gastroenterologie şi Hepatologie Iaşi 18.978 pacienţi dintre care pentru studiul de faţă au fost selectaţi 644 pacienţi la care rezultatul anatomopatologic a relevat cancer colorectal şi un alt lot de 279 pacienţi operaţi în Clinica nr.1 Chirurgie a Spitalului „Sf. Spiridon” Iaşi în perioada 2008-2010.

Cele 644 de cazuri au beneficiat toate de examen anatomo-patologic efectuat pe specimene rezultate în urma examenului colonoscopic iar cele 279 de cazuri au beneficiat pe lângă examenul histopatologic al tumorii primare şi de examenul histopatologic al metastazei la distanţă.

Realizarea studiului a necesitat cunoaşterea principalelor date clinice (vîrstă , sex, domiciliu, data diagnosticului, sediul anatomic al tumorii şi a aspectelor anatomopatologice tumorale – macroscpia, microscopia şi stadiul patologic. Pentru aceasta au fost studiate foile de observaţie a bolnavilor, registrul de examene endoscopice, registrul de protocoale operatorii şi registrul examenelor anatomo-patologice.

Prelucrarea datelor s-a efectuat cu ajutorul programului de statistic *S.P.S.S.* şi programului MS EXCEL 2007.

REZULTATE

Se remarcă faptul că frecvenţa sexului masculin în lotul de studiu este uşor mai crescută (59,63%). Repartiţia cazurilor în funcţie de sexul pacienţilor pe anii de studiu a evidenţiat o menţinere aproximativ constantă a frecvenţei cazurilor în perioada studiată cu excepţia anului 2000. În acest interval pacienţii de sex masculin au prezentat o frecvenţă uşor mai ridicată (50%-63,3%) comparativ cu frecvenţa pacienţilor de sex feminin (40%-50%), excepţie făcând anul 2000 când frecvenţa pacienţilor de sex masculin ce prezentau cancer colorectal a fost de 80,65%, valoare semnificativ mai mare comparativ cu valoarea corespunzătoare pacienţilor de sex feminin (19,35%).

Analiza distribuţiei cazurilor diagnosticate cu cancer colorectal în funcţie de mediul de provenienţă evidenţiază o frecvenţă a cazurilor din mediul rural de 32,6% valoare mică comparativ cu frecvenţa cazurilor din mediul urban (67,6%). Repartiţia anuală a cazurilor în funcţie de mediul de provenienţă duce la concluzia că pe toată perioada studiată au predominat cazurile din mediul urban, frecvenţa lor fiind de peste 51,6%.

Indicatorii statistici ai vârstei în funcţie de sexul pacienţilor evidenţiază valori mi-

nime de 19 ani atât la pacienţii de sex feminin cât şi la cei de sex masculin şi maxime de 86 ani, respectiv 87 ani pentru bărbaţi. Valoare mediană indică faptul că 50% dintre pacienţi au vârsta mai mică de 56 ani, aspect valabil pentru femei, iar pentru bărbaţi valoare mediană fiind 57 ani. Rezultatele testelor neparametrice de comparaţie şi corelaţie demonstrează pe de o parte diferenţa semnificativă a numărului de cazuri provenite din mediul urban comparativ cu cele provenite din mediul rural (χ^2=21,55, p=0,00303, 95%CI) şi tendinţa de creştere a numărului de cazuri din mediul urban în ultimii ani (r=0,539, p=0,0138). Aprecierile au fost făcute pentru un interval de încredere de 95%.

Compararea valorilor medii ale vârstei pentru cele două loturi analizate evidenţiază faptul vârsta medie a pacienţilor de sex feminin nu diferă semnificativ de vârsta pacienţilor de sex masculin. Vârsta medie a pacienţilor de sex masculin a fost de 63,7±12 cu valori minime de 19 şi maxime de 86 iar vârsta medie a pacienţilor de sex feminin a fost de 63,8±12,2 cu minim de 19 şi maxim de 87 ani.

Distribuţia pe segmente a cancerului colorectal (fig. 1) se prezintă astfel: rect 378 cazuri (58,70%), sigmoid si joncţiune rectosigmoidiană 88 cazuri (13.6%), colon descendent 23 (3,57%), colon transvers 80 cazuri (12,42%) şi colon ascendent 75 cazuri (11,65%).

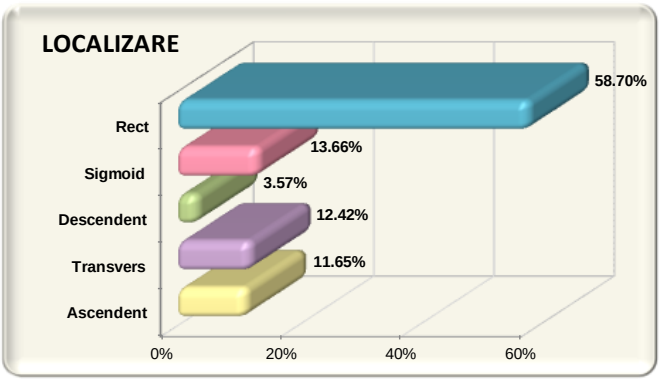

Fig. 1. Repartiţia cazurilor în funcţie de localizare

La nivelul colonului proximal (cec, colon ascendent, unghi hepatic, transvers şi unghi splenic) au fost identificate 24,07% cazuri de cancer colorectal, în timp ce la nivel distal am regăsit 75,9% din cazuri, valoare net superioară localizării proximale**.**

Analiza distribuţiei cazurilor în funcţie de localizare şi sexul pacienţilor evidenţiază prezenţa localizării pe colonul ascendent mai frecventă la sexul masculin 72% în timp ce la pacienţii de sex feminin această localizare este regăsită la 28% din cazuri. O frecvenţă similară, mai mare la pacienţii de sex masculin, o regăsim în cazul localizării carcinomului pe colonul transvers (67,5%) şi pe rect (58,99%). În cazul localizării pe sigmoid şi pe colonul descendent regăsim o frecvenţă uşor mai ridicată în rândul pacienţilor de sex feminin (52,27% respectiv 52,17%).

Studiul a demonstrat existenţa unei asocieri moderate între localizare şi grupa de vârstă a pacienţilor astfel, se remarcă faptul

că pe colonul descendent întâlnim numai pacienţi cu vârstă peste 50 ani în timp ce pe colonul transvers ponderea aparţine grupei de vârstă sub 50 ani (64%).

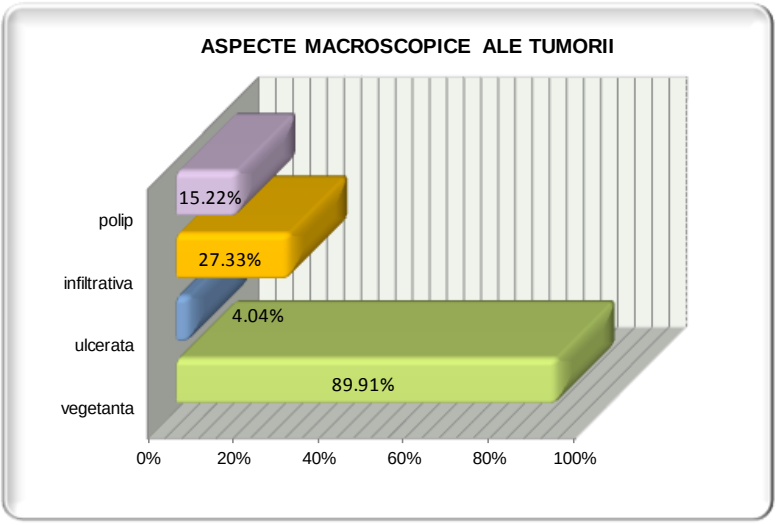

Fig. 2. Repartiţia cazurilor în funcţie de aspectele macroscopice

Analiza aspectelor macroscopice prezente la pacienţii lotului de studiu (fig. 2) a evidenţiat o frecvenţă mare a formelor vegetante (89,91%). Un procent semnificativ comparativ cu formele ulcerate (4,04%) îl prezintă polipii ce se regăsesc în proporţie de 15,22%. Formele infiltrative au fost prezente în proporţie de 27,33%.

În perioada analizată frecvenţa cazurilor în funcţie de aspectele macroscopice s-a schimbat semnificativ pentru formele infiltrative şi cele ulcerate evidenţiate colonoscopic. În cazul formelor infiltrative dacă în anul de început al studiului întâlneam 25,8% cazuri, procentul a crescut semnificativ atingând în anul 2004 un maxim de 44,7%, după care s-a înregistrat o uşoară scădere a numărului de cazuri. Pentru formele ulcerate se înregistrează o scădere bruscă a numărului de cazuri în ultimii 3 ani ai studiului frecvenţa ajungând la 0% (2005-2007). La începutul intervalului (2000) frecvenţa formelor ulcerate a fost de 16,1% iar în anul 2004 de 7,9%.

În tabelul I putem remarca faptul că dintr-un număr total de 76 cazuri de cancere colorectale prelevate din biopsii polipoide 64% erau formaţiuni polipoide, 28% polipi pediculaţi şi 8% polipi sesili.

TABELUL I

Reprezentarea grafică procentuală a tipurilor de polipi biopsiaţi

	2000	**2001**	**2002**	**2003**	**2004**	**2005**	**2006**	**2007**
Nr. total de polipi	2	3	7	8	9	12	15	20
Polipi pediculaţi	50 %	66,6 %	28,5 %	25 %	22,2 %	25 %	26,6 %	25 %
Polipi sesili	---	---	---	---	11,1 %	8,33 %	13,3 %	10 %
Formaţiuni polipoide	50 %	33,3 %	71,4 %	75 %	66,6 %	66,6 %	60 %	65 %

Studiul comparativ al vârstei pacienţilor în funcţie de dimensiunea polipilor colorectali evidenţiază faptul că pacienţii cu dimensiuni ale polipilor de peste 10mm au vârste semnificativ mai mari (vârsta medie 63,9 ani, p=0,00, 95%CI) comparativ cu vârsta pacienţilor prezintă dimensiuni mai mici de 10mm (55,5 ani – sub 5 mm respectiv 58,4 ani – 6÷10mm).

Din lotul studiat adenocarcinomul moderat diferenţiat reprezintă 46,43% , adenocarcinomul bine diferenţiat 42,24%, adenocarcinomul slab diferenţiat 7,14 % restul fiind reprezentat de adenocarcinomul mucinos, cel cu celule inel de pecete, adenoscuamos şi de carcinomul *in situ*.

Urmărind protocoalele operatorii a 279 pacienţi operaţi în Clinica nr.1 Chirurgie a Spitalului „Sf. Spiridon" Iasi în perioada 2008-2010 am efectuat un studiu privind rezultatele examenului anatomo-patologic a specimenelor tumorale rezecate chirurgical, a ganglionilor regionali precum şi a metastazelor la distanţă.

Stadializarea patologică a carcinoamelor conform criteriilor TNM (O.M.S.,2000) a fost urmatoarea:

- repartiţia cazurilor în funcţie de tumora primară: T1 12,18%, T2 18,27%, T3 59,19%, T4 10,39 %.
- repartiţia cazurilor în funcţie de ganglioni limfatici regionali: Nx 16,12%, N0 24,37%, N1 38,7%, N2 18,27%, N3 2,5%.
- repartiţia cazurilor în funcţie de metastazele la distanţă: Mx 69,17%, Mo 12,54% , M1 M1 18,27%.
- repartiţia cazurilor în funcţie de gradul histologic: G1 18,27% , G2 56,98% , G3 24,73%.
- repartiţia cazurilor în funcţie de stadiul CCR: Stadiul I 16.48%, Stadiul II 30.46%, Stadiul III 42.65%, Stadiul IV 10.39%.

DISCUŢII

Organizaţia Mondială a Sănătăţii (O.M.S., 2000) a estimat 875000 de cazuri de cancer colorectal în întreaga lume în 1996, reprezentând aproximativ 8,5% din toate cazurile noi de cancer. Acesta este cea mai frecventă cauză de deces prin cancer în ţările industrializate din Europa (58300 decese/an) şi SUA (156000 cazuri noi/an) (4). Deşi considerată multă vreme o tumoră a vârstei înaintate, carcinomul colorectal devine tot mai frecvent un diagnostic al adultului în plină activitate, formele grave (tipuri histologice slab diferenţiate şi nediferenţiate) apărând chiar sub 40 de ani.

În America, cancerul colorectal reprezintă a doua cauză de deces, numărul de noi cazuri anuale fiind aproximativ egal pentru bărbaţi si femei (5). Este principala boală în ţările din vestul Europei fiind a doua cauză de deces prin cancer;prevalenţa ei este în creştere (6).

În Anglia este principala boală, cu 30.000 noi cazuri diagnosticate în fiecare an şi aproximativ 17.000 de decese/an. Vârsta medie a incidenţei este în decada a şaptea fiind cea mai obişnuită cauză de deces prin cancer după cel pulmonar la bărbaţi Şi după cel de sân la femei. (6). Peste 90% din cazuri sunt sporadice şi cel mai frecvent tip, responsabil pentru 95% din cazuri, este adenocarcinomul.

În Australia, cancerul colorectal este a doua cauză de deces după cancerul pulmonar (7). Aproximativ 50% din cancere sunt atribuite factorilor alimentari şi aproximativ 15-20% factorilor genetici inclusiv sindroamele familiale cu risc înalt.

În Italia cancerul colorectal este al patrulea tip de cancer in funcţie de incidenţă şi a doua cauză de deces prin cancer (8).

Cu aproximativ 57.000 de noi cazuri în fiecare an, reprezintă cel mai frecvent tip

de cancer în Germania (9), fiind înaintea cancerului de sân (aproximativ 46.000 noi cazuri) şi a cancerului pulmonar (aproximativ 37.000). Cu toate ca incidenţa globală este in creştere, în Germania incidenţa este mai crescuta la bărbaţi. Rata mortalităţii (aproximativ 26.500 decese anual) este in declin la bărbaţi în ultimii 10 ani şi la femei în ultimii 20 de ani.

În România, incidenţa cancerului colorectal (CCR) este considerată medie (18,55/100.000 locuitori), constatându-se, în ultimii 10 ani, o creştere marcată a acesteia, de la 10,1 in 1989 la 18,55 în 1999. Incidenţa cancerului colorectal reprezintă 8% din incidenţa neoplaziei, în general. Atât la bărbaţi, cât şi la femei, este pe locul 3 în România după cancerul bronhopulmonar şi gastric şi, respectiv, sân şi uter (10).

Cancerul colorectal rămâne incontestabil o importantă problemă de sănătate publică.

CONCLUZII

Se observă o creştere a numărului de cazuri în ultimii ani ai perioadei studiate (2005, 2006, 2007) în raport cu anii de început (2000, 2001), ajungându-se în anul 2007 la 6,82% de cazuri cu cancer colorectal din numărul total de colonoscopii efectuate în timp ce în anul 2000 frecvenţa a fost de 1,52%.

Tendinţele în evoluţia incidenţei neoplasmului de colon ne arată că în anii marginali ai studiului (2000-2007) numărul cazurilor cu tumori slab diferenţiate a rămas relativ constant, în timp ce incidenţa neoplasmelor bine şi moderat diferenţiate a crescut de aproximativ 7 şi, respectiv, 4 ori. În studiul nostru se observă creşterea numărului de cazuri în ultimii 3 ani.

Nici o formă nu prezintă o predispoziţie semnificativă pentru pacienţii de un anumit sex, cu alte cuvinte forma macroscopică nu se asociază cu sexul pacienţilor. Carcinoamele colorectale prezintă o incidenţă crescută la pacienţii peste 60 ani.

Analiza aspectelor macroscopice prezente la pacienţii lotului de studiu a evidenţiat o frecvenţă mare a formelor vegetante (89,91%). Un procent semnificativ comparativ cu formele ulcerate (4,04%) îl prezintă polipii ce se regăsesc în proporţie de 15,22%. Formele infiltrative au fost prezente în proporţie de 27,33%.

Nu există o corelaţie semnificativă între localizarea tumorii şi aspectul macroscopic al acesteia.

NOUTĂȚI

EFECTELE CONTAMINĂRII CU SALIVĂ ŞI SOLUȚIILE DE CURĂȚARE ASUPRA ADEZIUNII LA DENTINĂ A SISTEMELOR AUTOGRAVANTE

Contaminarea cu salivă reprezintă o problemă frecventă a stomatologiei restaurative, a cărei rezolvare a devenit şi mai importantă odată cu extinderea tehnicilor adezive. Contaminarea substratului aderent cu salivă, sânge sau fluid sulcular compromite sau diminuează semnificativ adeziunea materialului de restaurare, tehnicile de izolare sunt consumatoare de timp şi uneori ineficiente iar soluțiile utilizate pentru decontaminare interferă ele insele adeziunea. Studii recente par să indice faptul că unele sisteme adezive autogravante, deşi considerate mai puțin eficiente decât cele tradiționale cu gravaj total, de ar putea fi mai puțin sensibile la contaminare. Acest studiu a determinat efectul contaminării cu salivă şi al utilizării unor soluţii de curăţare asupră rezistenţei adeziunii asupra unor astfel de sisteme autogravante. Şaptezeci şi cinci de molari umani au fost secţionaţi pentru a expune dentina medie coronară şi au fost împărţiţi aleatoriu în cinci grupe: nici o contaminare, contaminarea saliva fără curăţare, contaminare cu salivă şi curăţare cu apă, contaminare cu salivă şi curăţare cu clorhexidină 2%, şi contaminare cu salivă şi curăţare cu hipoclorit de sodiu 5%. Câte o treime dintre eşantioanele din fiecare grup au fost tratate cu Adper Prompt L-Pop (3M ESPE), Adper Easy Bond (3M ESPE), respectiv Clearfil SE Bond (Kuraray). Probele au fost restaurate cu materiale compozite şi procesate pentru testarea rezistenţei adeziunii la microtensiune. Rezistenţele medii ale adeziunii au variat de la 17.3 MPa, pentru Adper Prompt L-Pop după curăţarea cu apă la 69.3 MPa pentru Clearfil SE Bond după curăţare cu apă. Pentru toate cele trei sisteme adezive, nu au existat diferenţe statistic semnificative între grupurile contaminate cu salivă, grupurile contaminate şi apoi curăţate, şi grupurile necontaminare. Rezultatele acestui studiu susţin ipoteza că performanţele sistemelor adezive testate nu sunt influenţate în mod semnificativ de contaminarea cu salivă sau de substanţele utilizate pentru curăţarea plăgii dentinare (Sheikh H , Heymann HO , EJ Jr Swift , TL Ziemiecki , AV Ritter . Effect of saliva contamination and cleansing solutions on the bond strengths of self-etch adhesives to dentin. *J Esthet Restor Dent* 2010; 22(6): 402-410).

EXPERIMENTAL RESEARCH ON THE INFLUENCE OF STRESS FACTORS IN AN ANIMAL MODEL OF HYPERTENSION (Abstract): **Aim**: to investigate the influence of some stress factors in endothelin-1–induced hypertension. **Material and methods:** The experiment was carried out on Wistar rats, treated intraperitoneally, for 4 weeks, as follows: **Group 1:** saline solution (0.5ml/100g weight); **Group 2**: saline solution + stress; **Group 3**: Endotelin-1; **Group 4**: Endotelin-1 + stress; **Group 5**: Endotelin-1 + cholesterol diet (0,2g/kbw/day); **Group 6**: Endotelin-1 + cholesterol diet + stress. Endotelin-1 0.25nmol/kbw was initially administered, followed by 0.5nmol/kbw 15 min later, 2 times/week. Stress-inducing factors were immobilization and water immersion. In the 28^{-th} day of the experiment blood pressure was measured and blood samples were taken from the retro-orbitary plexus to assess plasma cortisol, blood count, phagocytic capacity of peripheral neutrophils, and serum complement activity. **Results and discussions**: Repeated administration of endotelin-1 determined an increase in blood pressure, statistically significant in stress conditions comparing to non-stressed animals. Our study proved a decrease of plasma cortisol, total leukocyte count, phagocytic capacity of peripheral neutrophils, without significant alterations in serum complement activity. **Conclusions**: Chronic exposure to complex stress conditions in rats with endothelin-1-induced hypertension determined a decrease of plasma cortisol levels, effect correlated with elevated blood pressure and decrease in the number and phagocytic function of peripheral neutrophils. **Key words**: STRESS, CORTISOL, BLOOD PRESSURE

Stresul reprezintă consecința lipsei de răspuns corespunzător a unui organism la agresiuni emoționale sau fizice. În general, stresul este determinat atât de factori interni, cât şi externi. Organismul uman răspunde la factorii stresori, prin activarea sistemului nervos şi a hormonilor specifici. În timpul unei reacții anxioase, printr-un lanț de stimulări ale sistemului nervos şi ale celui endocrin, sunt eliberați anumiți mediatori endogeni: catecolamine (adrenalină, noradrenalină), cortizol, vasopresină, ACTH, STH. Prima dintre substanțele eliberate este adrenalina, de către glandele suprarenale. Aceşti mesageri primari acționează asupra celulelor din diferite țesuturi şi organe, producând modificări funcționale, inițial, reversibile, apoi ireversibile. De exemplu, printre efectele rezultate în urma acțiunii catecolaminelor la nivelul inimii,

sunt: creşterea frecvenţei cardiace, a contractilităţii, a automatismului cardiac. La acelaşi nivel, cortizolul produce: creşterea debitului cardiac, creşterea răspunsului la catecolamine, hipervolemie (1,2).

Stresul eliberează catecolamine, care pot, indirect, să determine creşterea acizilor graşi şi a nivelului glucozei în sistemul circulator. Acestea pot fi convertite în lipide şi colesterol şi depozitate la nivelul pereţilor arteriali. Aceste depozite realizează o rezistenţă în fluxul circulator şi contribuie, astfel, la creşterea tensiunii arteriale. Stresul mental cronic creşte presiunea arterială, precum şi nivelul colesterolului, conducând, astfel, la hipertensiune arterială cronică şi dislipidemie. Studiile efectuate au pus în evidenţă existenţa unor corelaţii între diferitele tipuri de stres, reactivitatea organismului şi modificările presionale (3,4).

Scopul acestei cercetări a fost de a stabili influenţa unor factori de stres pe un model de hipertensiune arterială indusă experimental.

MATERIAL ŞI METODĂ

Au fost utilizate 6 loturi de câte 6 şobolani Wistar, cu greutate cuprinsă între 180-200g, cu repartiţie uniformă pe sexe, proveniţi de la Institutul de Sănătate Publică din Iaşi, trataţi intraperitoneal, timp de 28 de zile, începând cu ora 8 dimineaţa, conform schemei:

L1 (SF): Ser fiziologic (0,5 ml/100g c/zi);

L2 (SF+s): Ser fiziologic + stres (indus de imobilizare şi imersie în apă);

L3 (ET-1): Endotelină-1 (iniţial 0,25 nmol/kgc, iar după 15 min 0,5 nmol/kgc, 2 administrări pe săptămână);

L4 (ET-1+s): Endotelină-1 + stres;

L5 (ET-1+col): Endotelină-1 + dietă cu colesterol (0,2 g/kgc/zi);

L6 (ET-1+col+s): Endotelină-1 + dietă cu colesterol + stres.

După 28 de zile de tratament, s-a recoltat sânge din plexul retroorbitar (respectând condiţiile de etică a experimentului pe animale de laborator) şi au fost determinaţi următorii parametri: tensiunea arterială, nivelul cortizolului sanguin, formula leucocitară, capacitatea de fagocitoză a polimorfonuclearelor neutrofile (PMN) din sângele periferic, activitatea complementului seric.

REZULTATE ŞI DISCUŢII

Modelul experimental realizat poate fi folosit cu succes, ca o alternativă la achiziţionarea de şobolani modificaţi genetic, pentru a dezvolta hipertensiune arterială, ca şi pentru studierea implicării endotelinei în modelele de hipertensiune arterială indusă experimental la animale de laborator.

Stresul cronic realizat a antagonizat efectele imunomodulatoare ale endotelinei-1, de inducere a leucocitozei, cu creşterea absolută a PMN şi a funcţiilor fagocitare ale acestora.

Valorile absolute ale tensiunii arteriale au fost determinate cu sfigmomanometrul HAMEG (fig. 1).

Administrarea repetată de endotelină-1 determină creşterea valorilor tensiunii arteriale la şobolanii Wistar. Valorile tensiunii arteriale sunt semnificativ statistic crescute la animalele de laborator expuse la stres, comparativ cu valorile acestui parametru la animalele care nu au fost menţinute în aceste condiţii experimentale. Cele mai ridicate valori ale tensiunii arteriale au fost înregistrate la şobolanii Wistar cărora li s-a administrat endotelină-1, dietă cu colesterol şi au fost expuşi unui stres cronic.

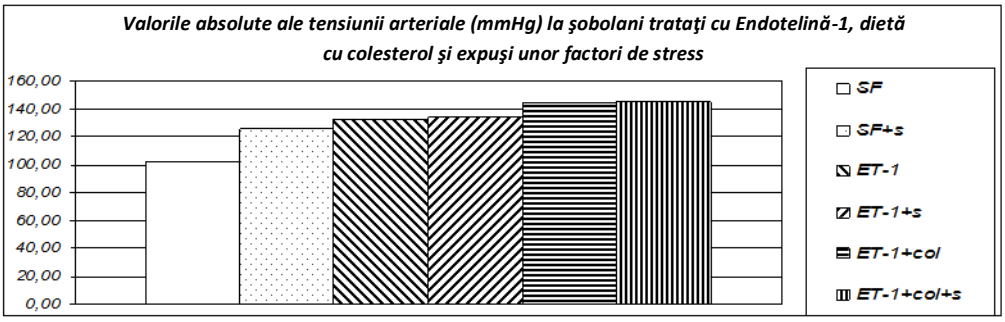

Fig. 1. Valorile absolute ale tensiunii arteriale după 28 de zile

În condițiile experimentale ale stresului cronic realizat, s-a constatat o scădere a valorilor cortizolului plasmatic (fig. 2), comparativ cu lotul martor, acest efect fiind semnificativ statistic mai puternic la animalele cu HTA indusă experimental, cu dietă cu colesterol plus menținerea în condiții de stres. Datele din literatura de specialitate demonstrează că, în cazul persoanelor stresate, valorile cortizolului se mențin crescute pe tot parcursul zilei (5). Tensiunea arterială, de asemenea, creşte. Când stresul devine cronic, rezervele de cortizol scad. Astfel, dacă, inițial, secreția hormonului este ridicată, în timp, ea devine inexistentă (2).

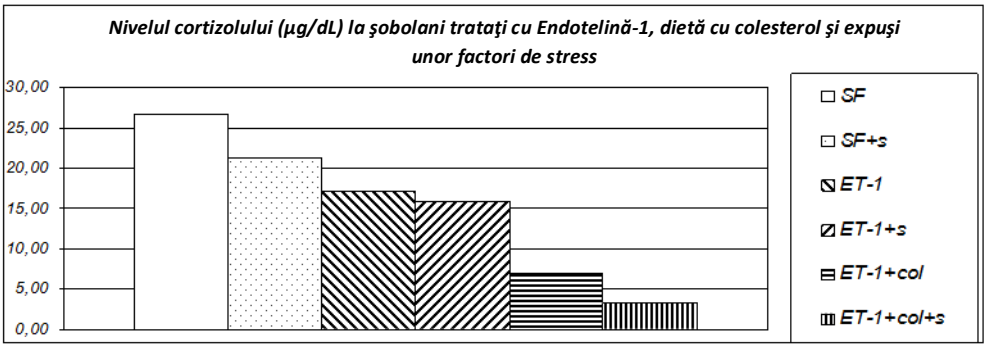

Fig. 2. Nivelurile cortizolului sanguin după 28 de zile

În condițiile experimentale realizate, s-a constatat o scădere a numărului total de leucocite (fig. 3), rezultată din scăderea PMN (fig. 4), precum şi o scădere a capacității de fagocitoză a PMN din sângele periferic (fig. 5), comparativ cu lotul martor. Astfel, stresul cronic a indus nu numai scăderea nivelului sanguin al cortizolului, ci şi o scădere semnificativă statistic a numărului şi funcției PMN. Administrarea repetată de endotelină, asociată sau nu cu dieta cu colesterol, nu a determinat modificări semnificative ale acestor parametri.

Nu s-au constatat modificări semnificative statistic ale activității complementului seric.

Condițiile de stres cronic în care au fost menținute animalele cu HTA indusă experimental cu endotelină-1 şi supuse unei diete cu colesterol au condus la creşterea presiunii arteriale şi la o scădere a nivelului cortizolului sanguin.

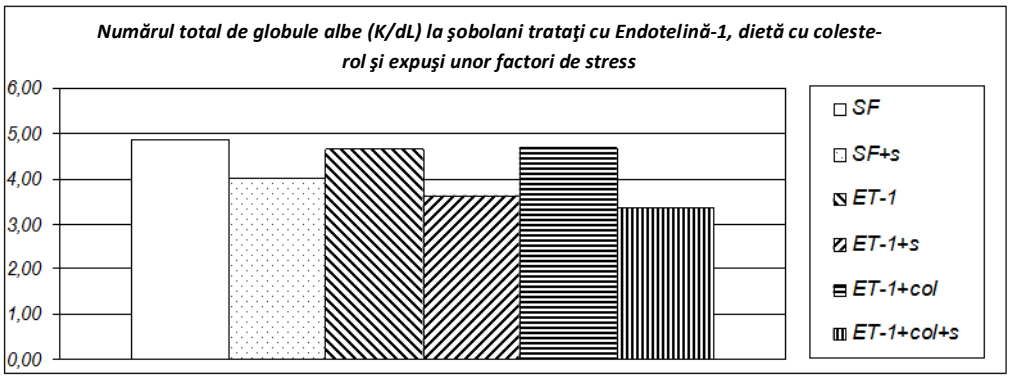

Fig. 3. Valorile leucocitelor după 28 de zile

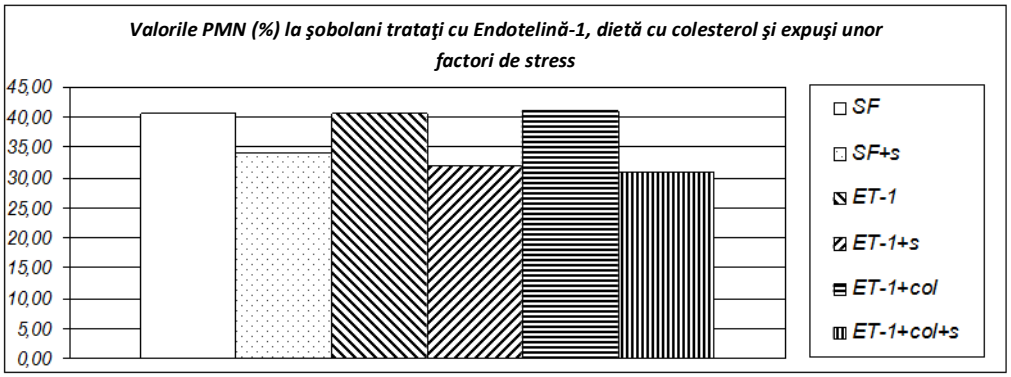

Fig. 4. Valorile PMN după 28 de zile

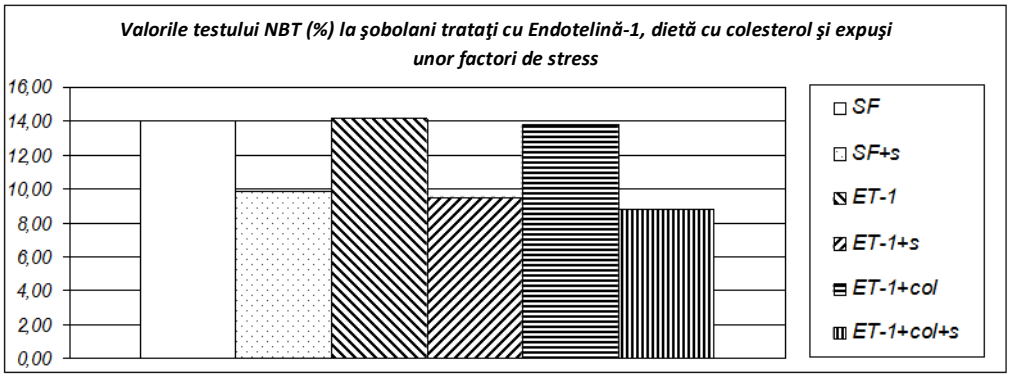

Fig. 5. Valorile testului NBT după 28 de zile

CONCLUZII

Administrarea repetată de endotelină-1 a determinat creşterea valorilor tensiunii arteriale la şobolanii Wistar. Valorile obținute au fost semnificativ statistic crescute la şobolanii expuşi la stres, comparativ cu nivelurile tensiunii arteriale la animalele care nu au fost menținute în aceste condiții experimentale. Cele mai ridicate valori ale tensiunii arteriale au fost înregistrate la

şobolanii Wistar cărora li s-a administrat endotelină-1, dietă cu colesterol şi au fost expuşi unui stres cronic.

În condițiile experimentale ale stresului cronic realizat, s-a constatat o scădere a valorilor cortizolului plasmatic, comparativ cu lotul martor, acest efect fiind semnificativ statistic mai puternic la animalele de laborator cu HTA indusă experimental, menținute în condiții de stres şi având, ca factor de risc, dieta cu colesterol.

În condițiile experimentale realizate, s-a constatat o scădere a numărului total de leucocite, rezultată din scăderea PMN, precum şi o scădere a capacității de fagocitoză a PMN din sângele periferic, comparativ cu lotul martor. Stresul cronic a indus, deci, scăderea nivelului sanguin al cortizolului, corelată cu o scădere semnificativă statistic a numărului şi funcției fagocitare a PMN. Condițiile experimentale de stres cronic realizate au menținut imunosupresia indusă, inițial, de cortizol, pentru ca, la finalul studiilor, să determine scăderea nivelului plasmatic al cortizolului, conducând la concluzia reducerii rezervelor din acest glucocorticosteroid. Administrarea repetată de endotelină, asociată sau nu cu dieta cu colesterol, nu a determinat modificări semnificative statistic ale acestor parametri. Nu s-au constatat modificări semnificative statistic ale activității complementului seric.

PSYCHOLOGICAL APPROACH IN THE MANAGEMENT OF IRRITABLE BOWEL SYNDROME (Abstract): Irritable bowel syndrome has a worldwide prevalence that affects up to 10-15% adults of all ages, being related with a significant health care and economic involvement. The factors that play a role in the alteration of the brain-gut axis include genetic predisposition, an intestinal infection prior to symptoms onset, or chronic stressful life events. People with IBS should discuss with the gastroenterologist in developing a management plan to address these issues effectively and improve quality of life. An important step for the diagnosis is to look for symptoms and signs that are suggestive for other conditions, like inflammatory bowel disease, or celiac disease. The treatment for IBS includes life style changes, medication, counseling with psychological and behavioral therapies. **Keywords:** IRRITABLE BOWEL SYNDROME, PSYCHOLOGICAL, MANAGEMENT.

INTRODUCTION. EPIDEMIOLOGICAL DATA

Irritable bowel syndrome (IBS) is a long-term recurrent disorder of gastrointestinal (GI) functioning with disturbances of gut motility. It is characterized by abdominal pain or discomfort, bloating and altered bowel habit (chronic or recurrent diarrhea, constipation, or both – either mixed or in alternation).

IBS has a significant worldwide prevalence that affects up to 10-15% of adults and between 25 and 45 million people in the United States. It involves persons of all ages and about 2 out of 3 IBS patients are females. This functional disease can also severely compromise a person's quality of life, being the second cause of absenteeism from work after the common cold (1).

Studies have shown that IBS patients have an increased number of outpatient health care visits, diagnostic tests, and even surgeries (2). The symptoms are the consequence of increased sensitivity to gas, food, or stool in the bowel and appear from disturbances in colonic motility. Finally, the bowel tends to be overly reactive to various factors (emotional stress, GI infections, eating, gaseous distension, or menstrual period) which can bring about or amplify the symptoms (3).

ETIOPATHOGENESIS

There are possible genetic factors and

prior adverse life experiences that can predispose to IBS, but the exact cause of it is not completely understood.

Brain-gut interactions

The altered patterns of colonic motility appear to be due to disruptions in the communication between the brain and gut, the interaction being known as the brain-gut axis. These bi-directional interactions respond to any potential disturbance or stressor and are important in maintaining normal bowel function. The factors that may play a role in the alteration of the brain-gut axis include: genetic predisposition, intestinal infection prior to symptom onset, chronic stressful life events, or other psychosocial factors.

PSYCHOLOGICAL FACTORS

Some people with IBS report symptoms such as anxiety, or depressed mood that occur mainly in persons with more severe symptoms and in patients seen in tertiary medical care referral centers. Psychological factors are not a primary cause of IBS, but they may influence how a person seeks to manage and deal with IBS (4).

Emotional distress may be associated with a worsening of IBS symptoms that may induce an anticipatory anxiety due to the severity, unpredictability, and negatively perceived consequences of having an "attack." This may result in continuing symptom occurrence and set up a vicious cycle between emotional distress, symptoms, and personal management strategies.

Many people experience abdominal pain and constipation or diarrhea without any evidence of anxiety, depression, or other psychological symptoms. This response in people with IBS is more pronounced on a recurrent or chronic basis and therefore, they are more likely to experience worse symptoms when they are exposed to a significant stressor.

Addressing these issues with an empathetic doctor, who can refer the patient for counseling, would improve IBS symptoms and daily function. In patients with IBS there is increased GI response to stress which basically represents anything that can stimulate the GI tract, including: diet, psychological stress, hormonal changes, physical activity that has been shown to increase motility and sensation of the colon to a greater degree in these patients.

Stress disturbs the balance between brain and body, with or without conscious feelings of anxiety, distress, or anger. It can be acute (short term) or chronic (more than three months), ranging from daily hassles to life-threatening events. People presenting IBS should work with their health care providers in developing a management plan to address these issues effectively, in order to decrease symptoms and improve, overall, quality of life (5).

DIAGNOSIS

The first step in making a positive diagnosis of IBS is for the doctor to identify if an individual has the symptoms of IBS. This is best determined by the use of the Rome Criteria, which is a collection of the most common symptoms that typify the disorder. This includes abdominal pain for several months that is associated with two of the following: the pain is relieved by defecation, the pain is associated with an increase or decrease in stool frequency, and/or the pain is associated with the stools becoming harder or softer in consistency (6).

The next important step is to look for signs and symptoms that are suggestive of a condition other than IBS, such as in-

flammatory bowel disease (IBD), or celiac disease which have been referred to as "alarm signs" or "red flags." They include: anemia and other abnormal blood tests, blood in the stool, unexplained weight loss, fever, new onset of symptoms at the age of 50 or older, family history of IBD, celiac disease, or colon cancer. When these symptoms and signs occur, they should be brought immediately to the attention of a doctor who may perform colonoscopy, upper endoscopy with small bowel biopsy, abdominal ultrasound and additional tests. Colonoscopy may also be done for younger people, particularly if the "red flags" or the doctor's judgment lead to the suspicion of other bowel diseases, such as IBD (7). It was noted that lymphocytic or microcytic colitis and nonspecific inflammation only occurred in patients with diarrhea-predominant IBS, and hence it was recommended that colonoscopy, when required, should include random colonic biopsies. Therefore, according to the American College of Gastroenterology guidelines, colonic investigation of diarrhea-predominant IBS and mixed diarrhea and constipation-type IBS subgroups with barium enema or CT colonography is not appropriate because of inability to perform random biopsies (8).

TREATMENT

Getting the IBS improvement means understanding that IBS is a sensory and a complex motility disorder which may have physical and stress-related dimensions.

A strong partnership between a knowledgeable patient and an empathetic doctor can control over symptoms and produces significant improvement for individuals with IBS.

The first line of treatment for IBS includes general measures such as: establishing an effective patient-physician relationship, obtaining education about IBS, and implementing lifestyle changes, which may be associated with symptoms.

Lifestyle changes

Lifestyle refers in evaluation any dietary or stress-related factors that could lead to symptoms and discuss these with the gastroenterologist. If certain foods set off or worsen symptoms, they must be reduced or avoid, also if the abdominal discomfort or pain occurs after eating, it may be helpful to eat smaller and more frequent meals.

Increased stress may result in the onset or worsening of IBS symptoms and associated non-bowel symptoms such as fatigue or low energy. Proper rest and exercise can help reduce stress levels and positively influence IBS.

Taking into consideration that IBS is also a stress, learning more about the disorder by self-care and communicating effectively with a gastroenterologist can reduce that stress.

Medication

A thorough evaluation by a physician is an important step toward selecting the treatment that is most appropriate for individual circumstances.

If lifestyle changes do not completely relieve IBS symptoms, a number of medications may be helpful. Antispasmodics: otilonium, pinaverium, dicyclomine, hyoscyamine, cimetropium may relieve abdominal pain or discomfort, particularly if the symptoms occur soon after eating. Anti-diarrheal agents: loperamide (Imodium), diphenoxylate (Lomotil) can be effective in preventing and relieving symptoms of diarrhea but may not be as helpful for the pain.

Laxatives (Linaclotide) can help treat symptoms of constipation and should be used under the supervision of a physician. Non-absorbable antibiotic rifaximin is recommended for reduction of IBS symptoms, as well as bloating in non-constipated patients. The use of prebiotics, synbiotics and probiotics that modify the gut microbiota are suggested for overall symptom improvement in IBS patients. Tricyclic antidepressant (TCAs) and selective serotonin reuptake inhibitors (SSRIs) medications are helpful for people with IBS and psychological distress (9). Individuals who have not responded to lifestyle changes and careful use of medications should be evaluated by a physician who specializes in functional GI and motility or stress-related GI disorders.

Counseling

Psychological and behavioral therapies may be indicated and effective in certain individuals.

Cognitive behavioral therapy (CBT) allows the individual to regain personal skills as well as mental techniques to better manage the symptoms (10). Hypnosis is useful to reduce painful discomfort mostly in treatment resistant patients. Psychological therapies like CBT, hypnotherapy, relaxation training is suggested for overall symptom improvement in IBS patients (11). Interpersonal psychotherapy addresses stressful responses to interactions with others. Behavioral therapy or skilled counseling may help with self-understanding and with identifying personal traits or problems that can be dealt with. Talking to a professional allows discussions of personal matters without fear of recrimination or blame (which is what can happen when talking to family, friends, or colleagues) and often helps to mutually develop a program for change. The effectiveness of complementary and alternative medicine therapies such as Chinese herbal therapy, acupuncture, acupressure, mindfulness meditation, and yoga are being evaluated in IBS patients. Acupuncture studies have demonstrated that a positive provider-patient interaction during acupuncture treatment sessions is associated with a beneficial effect in IBS (12).

CONCLUSIONS

IBS is a condition with well-defined clinical features and specific diagnostic criteria.

Worldwide it is estimated that 10-15% of the population has IBS and about 2 out of 3 patients are females.

Stress does not cause IBS, but it can worsen or trigger symptoms because of the connection between the brain and the gut.

IBS can only be diagnosed by a professional doctor and involves the exclusion of other organic diseases by colonoscopy.

Psychological and behavioral therapies are available to manage symptoms for IBS, being indicated and effective in certain individuals.

NEWS

DIRECT ANTIVIRALS AND COAGULATION TO PATIENTS WITH HEPATITIS C VIRUS

The advent of direct-acting antivirals (DAAs) has been a major breakthrough in hepatology representing the therapeutic standard of care in patients with chronic hepatitis C virus infection over the past few years, providing safe and effective treatments for all patients with chronic HCV infection by increasing the sustained virological response rate to over 95%. A group of researchers from Italy (1) assessed the impact of DAA therapy on the coagulation parameters in viral cirrhosis C and sustained virological response. They investigated 28 patients on DAAs treatment and performed prothrombin-time, thrombin generation with and without thrombomodulin, whole-blood thromboelastometry, as well as the individual procoagulants (II, VIII, XIII, von Willebrand) and anticoagulants, antithrombin and protein-C. Patients had undetectable HCV-RNA at the end-of-treatment and at 12-weeks after end-of treatment. In conclusion, it has been demonstrated for the first time that AAD treatment in HCV positive patients and cirrhosis leads to improvement in pro- and anticoagulant status; does not substantially alter their balance but makes it more stable and less susceptible to disruption, as assumed before treatment (Tripodi A, D'Ambrosio R, Padovan L, *et al*. Evaluation of coagulation during treatment with directly acting antivirals in patients with hepatitis C virus related cirrhosis. *Liver Int* 2017; 37(9): 1295-1303).

ASSESMENT OF QUALITY OF LIFE OF THE ADJUVANT TREATMENT WITH TAMOXIFEN *VERSUS* AROMATASE INHIBITORS AT WOMEN WITH BREAST CANCER – A RANDOMIZED TRIAL (Abstract): **Purpose:** To evaluate and compare the impact on quality of life of tamoxifen and aromatase inhibitors (AIN's) in adjuvant settings, at women with breast cancer. **Methods**: From a total of 441 patients with breast cancer with hormonal treatment, were selected 177 of patients with adjuvant hormonal treatment (95 with tamoxifen treatment and 82 with AIN's treatment). These patients have completed the EORTC QLQ C-30 and EORTC QLQ BR23 questionnaires after 1 month of treatment (baseline), at 2 year of treatment with tamoxifen versus aromatase inhibitors (exemestane, anastrazole, letrozole). Mean change score from baseline and 2 years of treatment were compared in the both arms (tamoxifen vs. AIN's). **Results:** In the both arms, was observed a decreased QOL after 2 years comparative with the baseline. In the tamoxifen arm , global health status (GHS) and breast symptoms score (BRBS) were similar comparative with AIN's arm at baseline , with a similar status at 2 years measurement. **Conclusions:** The global health status (GHS) and breast symptoms score (BRBS) shows that there is no difference in the QOL at the women with breast cancer treated with tamoxifen , comparative with the women treated with AIN's . We conclude that AIN's did not have an adverse impact on overall QOL, comparative with tamoxifen, in adjuvant settings. Key words: QUALITY OF LIFE, TAMOXIFEN, BREAST CANCER, AROMATASE INHIBITORS

Tumorile maligne mamare sensibile la tratamentele hormonale care prezintă sau nu afectare a ganglionilor axilari sunt un grup heterogen de cancere. Ele au o diversitate prognostică, determinată şi de alţi factori prognostici, cum ar fi statusul HER2neu sau invazia vasculară. Tratamentul hormonal adjuvant în premenopauză este reprezentat de tamoxifen +/- supresia funcţiei ovariene. În postmenopauză, tratamentul hormonal adjuvant standard poate fi: tamoxifen 5 ani; inhibitori de aromatază 5 ani sau combinaţia tamoxifen 2 ani + inhibitori de aromatază 3 ani.

Tratamentul adjuvant cu tamoxifen timp de 5 ani de zile reduce riscul de recidivă a bolii şi de deces prin cancer mamar (1-5). Unul dintre efectele adverse majore ale terapiei cu tamoxifen este reprezentat de valurile de căldură (bufeuri), care duc deseori la discontinuarea tratamentului (6). Alte efecte secundare sunt evenimentele tromboembolice (7), atrofia mucoasei vaginale, sângerările vaginale, apariţia polipilor endometriali cu risc de transformare malignă (2,7%) (7). Efectele benefice ale

tratamentului cu tamoxifen sunt creşterea densităţii osoase la pacientele în postmenopauză (8) şi scăderea LDL în cadrul metabolismului lipidic (9).

Inhibitorii de aromatază blochează conversia hormonilor androgeni în hormoni estrogeni şi reduc nivelurile de hormoni estrogeni în plasmă (10). A treia generaţie de inhibitori de aromatază sunt inhibitorii nesteroidieni : letrozol, anastrazol, exemestane.

Tratamentul adjuvant cu anastrazol sau letrozol reduce riscul de recidiva a bolii în postmenopauză, comparativ cu tratamentul cu tamoxifen (11,12). Terapia secvenţială cu tamoxifen 2-3 ani apoi exemestane sau anastrazol până la 5 ani, scade riscul de recurenţă comparativ cu tamoxifen 5 ani (13). În ceea ce priveşte efectele secundare ale inhibitorilor de aromatază, artralgiile şi mialgiile, împreuna cu o creştere a incidenţei fracturilor, reprezintă evenimentele adverse principale (14,15).

Unul dintre scopurile tratamentelor specifice în cancer este menţinerea unei calităţi a vieţii acceptabilă. În acest sens, s-a încercat în studiul actual o evaluare a calităţii vieţii în cursul tratamentului adjuvant la pacientele cu cancer de sân. S-a evaluat calitatea vieţii atât în cadrul tratamentului cu tamoxifen, cât şi în cursul tratamentului cu inhibitori de aromatază (letrozol, anastrazol, exemestane).

PACIENŢI ŞI METODE

În cadrul Centrului de Oncologie Medicală Iaşi, în perioada 2001- 2009, dintr-un total de 2998 pacienţi aflaţi în evidenţă cu cancer, 629 de paciente au fost în evidenţă cu cancer de sân (366 au fost în premenopauză şi 256 de paciente în postmenopauza) (tab. I). Marea majoritate dintre aceste paciente au urmat tratamente multimodale (chirurgie, radioterapie, chimioterapie, hormonoterapie). Tratamentele hormonale au fost administrate la un număr de 441 de paciente cu cancer mamar. După stadiul bolii (TNM), pacientele tratate hormonal au fost preponderente în stadiul II şi III. În stadiul IV au urmat tratament hormonal paciente care aveau contraindicaţie la chimioterapie. Tratamentul adjuvant a fost aplicat în premenopauză timp de 5 ani cu tamoxifen şi în postmenopauză timp de 5 ani cu tamoxifen sau inhibitor de aromatază. Dintre pacientele care au urmat tratament hormonal în postmenopauză, au existat paciente tratate în

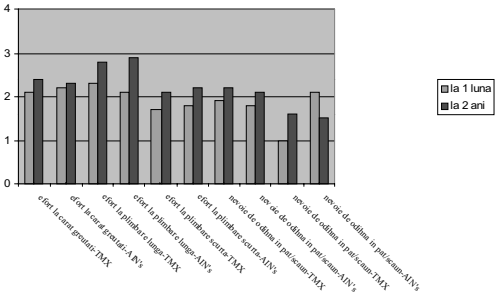

Fig. 1. Evaluarea efectelor adverse post-TMX/ AIN's

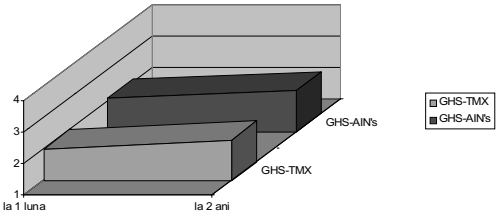

Fig. 2. Evaluarea GHS in terapia cu TMX/ AIN's

decursul celor 5 ani cu alternanţa tamoxifen – inhibitor de aromatază (tab. II).

Din totalul de 441 de paciente cu tratament hormonal, au fost selectate un număr de 177 de paciente (95 paciente în premenopauza şi 82 de paciente în postmenopauză) care au urmat tratament adjuvant cu tamoxifen sau/şi inhibitori de aromatază.

Lotul selectat, alcătuit din 177 de paciente, a fost format din paciente aflate în tratament hormonal astfel : premenopauză – 45 paciente stadiul II şi 56 paciente stadiul III, iar postmenopauză – 12 paciente în stadiul II şi 70 de paciente în stadiul III. Pacientele au avut, în momentul aplicării chestionarului de calitate a vieţii, vârste cuprinse între 29 şi 74 de ani.

Componenţa lotului evaluat din punct de vedere al calităţii vieţii a fost următoarea :

1. – bratul cu tratament cu tamoxifen - paciente care au urmat 5 ani adjuvanţa cu tamoxifen : stadiul II – 45 de paciente (31 în premenopauză şi 14 în postmenopauză) ; stadiul III – 50 de paciente (35 în premenopauză şi 14 în postmenopauză) - total 95 paciente

2. – bratul cu tratament cu AIN's - paciente care au urmat tratament cu inhibitori de aromatază (total 82 paciente) : stadiul II – 3 paciente care au primit exmestane 5 ani ; 2 paciente care au primit letrozol 5 ani ; 7 paciente care au primit 3 ani tamoxifen şi 2 ani letrozol (evaluarea a fost făcută în timpul tratamentului cu letrozol) ; stadiul III – 20 de paciente care au primit exemestane ; 14 paciente care au primit anastrazol ; 36 de paciente care au primit tamoxifel 3 ani şi apoi 2 ani letrozol (evaluarea s-a efectuat in timpul tratamentului cu letrozol)

La aceste paciente s-a aplicat, începand cu anul 2004 până în anul 2010, chestionarul EORTC-C30 şi chestionarul EORTC-BR23. În ceea ce priveşte EORTC-C30 s-a evaluat statusul sănătăţii globale (The global health status - GHS), iar în ceea ce priveşte chestionarul EORTC-BR23, specific cancerului mamar, s-a evaluat scorul simptomelor corelate cu cancerul de sân (breast symptoms score –BRBS).

Aplicarea chestionarelor EORTC-C30 si EORTC-BR23 a fost efectuată la 1 lună de la începerea tratamentului (cu tamoxifen sau AIN's) şi la 2 ani de zile de tratament cu medicaţia respectivă.

REZULTATE

În cazul chestionarului QLQ-C30, care evaluează global starea calităţii pacientelor cu cancer, s-a obţinut la o prima evaluare, un rezultat similar şi semnificativ statistic a evaluării simptomelor conţinute în chestionarul EORTC-C30 (fig. 1).

Scorul GHS la bratul care a primit tratament cu tamoxifen, comparativ cu bratul care a primit tratament cu AIN's, atât la 1 lună de la începerea tratamentului, cât şi la 2 ani de tratament a fost semnificativ statistic egal (fig. 2). S-au avut în vedere non--răspunsurile la chestionar.

Chestionarul EORTC-BR23 este specific simptomelor corelate cu cancerul mamar.

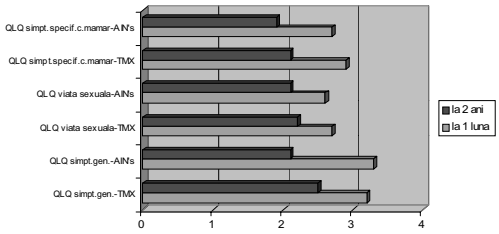

Fig. 3. Evaluarea simptomelor principale din chestionarul EORTC-BR23

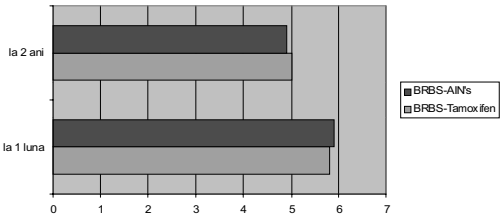

Fig. 4. Evaluarea BRBS – TMX/AIN's

S-a încercat evaluarea simptomelor dupa chestionarul EORTC-BR23. În ceea ce priveşte simptomele principale incluse în chestionarul EORTC-BR23, s-au obţinut rezultate similare semnificative statistic în ceea ce priveşte simptomele principale incluse în chestionar, la ambele brate (tratament cu TMX şi tratament cu AIN's). S-a avut în vedere de asemenea, în calculul statistic, non-răspunsurile la chestionare.

Chestionarul EORTC-BR23 a arătat rezultate statistice similare, demonstrând că la 1 lună şi la 2 ani de zile de tratament cu tamoxifen vs. AIN's, nu sunt diferenţe semnificative statistic între valorile scorului BRBS între cele 2 brate (paciente tratate cu tamoxifen vs. paciente tratate cu AIN's) (Fig.4).

Aplicarea chestionarelor EORTC-C30 si EORTC-BR23 a demonstrat de asemena şi faptul că la începutul tratamentului (1 lună), calitatea vieţii a suferit o scădere comparativ cu evaluarea la 2 ani de tratament în ambele brate – tamoxifen sau AIN's. Scăderea calităţii vieţii a fost vizibilă şi comparativ egala în ambele brate.

DISCUŢII

Rezultatele obţinute din studiul actual sugerează o calitate a vieţii asemănătoare în cadrul tratamentului cu AIN's, comparativ cu tratamentul cu tamoxifen. Ţinând cont de avantajele AINs în ceea ce priveşte supravieţuirea şi riscul mai scăzut de recidivă, se impune alegerea în postmenopauză a AIN's ca tratament de elecţie în adjuvantă, la pacientele în post-menopauză. Dacă avem în vedere studiile comparative între tratamentul adjuvant cu tamoxifen vs. letrozol (16), precum şi studiile comparative între tamoxifen vs. exemestane în adjuvanţă, utilizând chestionarul FACT-B (17) observam în literatura de specialitate o confirmare a non-inferiorităţii în ceea ce priveşte calitatea vieţii a tratamentului cu AIN's versus tratamentul cu tamoxifen. Într-adevar, tratamentul cu AIN's are marele dezavantaj al artralgiilor, dar faţă de tratametul cu tamoxifen, global, are acelaşi scor al calităţii vieţii. Studiul efectuat pentru evaluarea testelor cognitive, anxietate, depresie, astenie pentru a compara tratamentul cu exemestane vs. tamoxifen, au avut drept scop evaluarea simptomelor cu aceleaşi chestionare EORTC-C30 şi EORTC-B23, rezultatele fiind de non-inferioritate a exemestanului comparativ cu tamoxifenul în adjuvanţă, în ceea ce priveşte calitatea vieţii (18).

Rezultatele actuale demostrează non-inferioritatea tratamentului adjuvant cu AIN's comparativ cu adjuvanţă cu tamoxifen, în ambele categorii de vârstă (pre, post-menopauza, mai ales în postmenopauză).

O alta concluzie rezultată din studiul actual este scăderea calităţii vieţii la 2 ani comparativ cu nivelul iniţial, de la începerea tratamentului cu TMX sau AIN's, nivelul calităţii vieţii în ambele brate fiind egală.

CONTRIBUTION OF IMMUNIZATION AGAINST STREPTOCOCCUS PNEUMONIAE AND HEMOPHILUS INFLUENZAE TYPE B IN REDUCING PEDIATRIC RESPIRATORY MORBIDITY (Abstract). **Aim:** To highlights the peculiarities of acute respiratory infections and the possible complications in vaccinated children compared with unvaccinated children. **Material and methods:** This retrospective study included 346 patients aged 1 to 6 years, followed in a general practitioner center from an urban area. The cohort study was analyzed for immunizations and severe respiratory pathology requiring hospitalization or antibiotic therapy until the time of study. **Results**: Out of the 346 children surveyed, 20 (5.78%) presented ARI, according to the criteria we initially set for the selection, 21 (6.06%) presented otitis, 11 (3.17%) were hospitalized for respiratory tract infections, while 84.97% did not experience complicated respiratory pathology. In the age group 1-2 years old, from the 58 children vaccinated against Hib, but not against S. pneumoniae, 46 did not show severe respiratory pathology (79.31%), while the remaining 12 children (20.68%) recorded hospitalizations, otitis and respiratory infections that required antibiotic treatments. Of the 37 children aged 2-3 years, who were vaccinated against Hib, but not against S. pneumoniae, 32 did not have severe respiratory pathology (86.48%) and 5 children (13.51%) have a higher susceptibility. The distribution of 346 children according to respiratory pathology and vaccines showed that approximately 83% of non-vaccinated children developed respiratory pathology, while this pathology was present in less than 15% of the vaccinated children (p=0.001). **Conclusions**: We concluded that respiratory pathology was more prevalent in unvaccinated children comparing to vaccinated children. **Keywords**: VACCINATION, CHILDREN, RESPIRATORY DISEASE.

Acute respiratory infections are the most common cause of addressability in pediatric services. Vaccination is one of the most effective methods of prophylaxis, both in terms of effectiveness and cost, helping to reduce morbidity and mortality from ancient times. Each country has national vaccination programs established according to the epidemiological context of the region to which it belongs, with early childhood vaccination and the immunization of individuals at risk. The World Health Organization regularly develops strategies to increase vaccine coverage and

reduce the incidence of diseases that can be prevented.

Due to vaccine products availability to a large number of individuals, protection is extended to the entire community, through the phenomenon of "cohort immunity". When the majority of a population is vaccinated, even non-immunized or ineligible immunization (pregnant, immunocompromised) will be protected against the infectious agent because its spread is limited (1, 2).

Regarding vaccine-preventable diseases, the epidemiological situation in our country is similar to other countries in Europe, but there are also some exceptions. According to the dates in 2013, in Romania the incidence of tuberculosis is among the highest registered at European level, being reported cases of multidrug-resistant or antibiotics extensively resistant. Also, 1 out of 4 children who lose their life in their first year of birth die from respiratory illnesses, which are caused to a large extent by pneumococcus. Nowadays, among the preventive diseases by vaccination, pneumococcal disease is the main cause of global mortality in children under 5 years of age. Since February 2016, Romania has been experiencing a measles epidemic, with new cases still occurring, despite the strengthening of vaccination prevention measures (3).

In Romania, the national vaccination scheme, according to the Order of the Ministry of Health no. 386 of 31.03.2015 contains the following vaccines: tuberculosis vaccine (BCG - bacillus Calmette-Guérin - vaccination), HepB (hepatitis B), DTPa-IPV-Hib-HepB (diphtheria - tetanus - pertussis - poliomyelitis - *Hemophilus influenzae* type B - hepatitis B infection), ROR (rubella - mumps - measles) and PCV (pneumococcal vaccine). The optional vaccines currently available on the Romanian pharmaceutical market are those against: Rotavirus infection, varicella-zoster virus, hepatitis A or human papillomavirus (HPV) disease.

The aim of our study was to highlights the peculiarities of acute respiratory infections and the possible complications in vaccinated children compared with unvaccinated children.

MATERIAL AND METHODS

This retrospective study included 346 patients aged 1 to 6 years, followed in a general practitioner center from an urban area. The cohort study was analyzed for immunizations and severe respiratory pathology requiring hospitalization or antibiotic therapy until the time of study.

Inclusion criterion was age between 1 and 6 years of age in the course of the study (1st-31st December 2017).

Exclusion criterion were lack of appropriate data recorded in the observation sheets: new children in evidence or children who have not been present at the family medicine cabinet in the past year, lacking prophylactic mandatory controls and lacking accurate evidence and complete their pathological antecedents.

The cohort was divided into age groups. The diseases followed in the study were respiratory and otolaryngology (ENT) pathology. Moreover, the study cohort was divided into: "acute respiratory infections" (ARI), "Otitis", "Hospitalized", and "No serious respiratory diseases" groups. In the ARI group were included those children with more than three infectious episodes per year that required ambulatory antibiotic therapy, in the "Otitis" group children with at least three episodes of otitis media and in

the "Hospitalized" group those with at least one admission for acute respiratory tract infections. In those cases that have m*et al*l three conditions or two of them, we placed the children in the group with more numerous infectious episodes or higher severity (multiple days of hospitalization, antibiotic treatment extended over 10 days, use of two to three antibiotics per infectious episode).

RESULTS

The 346 cases of the study cohort were initially divided by gender and age groups, resulting in a homogeneous distribution (p = 0.583) (tab. I).

TABLE I

Distribution by age and gender

Age	Girls (n=162)		Boys (n=184)		All (n=346)	
	n	%	n	%	n	%
1-2 years	35	21.6	45	24.5	80	23.1
2-3 years	31	19.1	32	17.4	63	18.2
3-4 years	27	16.7	41	22.3	68	19.7
4-5 years	38	23.5	37	20.1	75	21.7
5-6 years	31	19.1	29	15.8	60	17.3

From the immunization point of view, the distribution of cases is as follows in table II. Vaccination against *Hemophilus influenzae* type b (Hib) was included in the national scheme for all children of the study group, while ant pneumococcal vaccination was part of the optional immunizations until October 2017, justifying the significantly lower number of cases vaccinated. Regarding the refusal of any vaccination, we did not record in any case religious or cultural reasons, only misinformation from sources other than scientifically validated data.

TABLE II

Distribution by age, gender and vaccinations

Age	Hib + Antipneumococic +		Hib + Antipneumococic -		Unvaccinated	
	Girls	Boys	Girls	Boys	Girls	Boys
1-2 years	12	8	23	35	0	2
	28.6%	19.5%	19.5%	25.2%	0.0%	50.0%
2-3 years	11	14	19	18	1	0
	26.2%	34.1%	16.1%	12.9%	50.0%	0.0%
3-4 years	8	10	18	29	1	2
	19.0%	24.4%	15.3%	20.9%	50.0%	50.0%
4-5 years	3	8	35	29	0	0
	7.1%	19.5%	29.7%	20.9%	0.0%	0.0%
5-6 years	8	1	23	28	0	0
	19.0%	2.4%	19.5%	20.1%	0.0%	0.0%
TOTAL	**42**	**41**	**118**	**139**	**2**	**4**

In the table above, children with immunization against *Hemophilus influenzae type* b and Streptococcus pneumoniae are marked "Hib +" and "Antipneumococcic +" and "Non-vaccinated" children those who have not been vaccinated, respectively. The latter include cases where the family refused by informed consent to carry out any vaccine, including those in the national scheme.

Hib +, Anti-pneumococcal vaccination + was predominates in girls aged 1 to 2 years (28.6%) and 2 to 3 years (26.2%), while Hib +, Antipneumococcic - vaccination in the age group 4 to 5 years (29.7%) ($p = 0.05$).

In boys, the proportion of Hib + Antipneumococcic + vaccinated predominates in the 2 to 3 years (34.1%) and 3 to 4 years (24.4%) groups, and the proportion of vaccinated and non-immunized children in the 1 to 2 years group (25.2 %); also, we find 4 unvaccinated children ($p = 0.004$).

Furthermore, we divided the 346 children according to the presence or absence of complicated respiratory or ENT pathology, in order to subsequently see how it correlates with immunizations. Thus, the distribution according to age and respiratory or ENT pathology requiring antibiotics or hospitalization is shown in the table III.

TABLE III

Distribution of children by age and respiratory or ENT pathology

Age	ARI	Otitis	Hospitalized	No serious respiratory diseases
1-2 years	6	4	5	65
2-3 years	4	4	1	54
3-4 years	3	5	1	59
4-5 years	5	4	2	64
5-6 years	2	4	2	52
TOTAL	**20**	**21**	**11**	**294**

Therefore, out of the 346 children surveyed, 20 (5.78%) presented ARI, according to the criteria we initially set for the selection, 21 (6.06%) presented otitis, 11 (3.17%) were hospitalized for respiratory tract infections, while 84.97% did not experience complicated respiratory pathology.

Next, children were analyzed for the above-mentioned pathology correlated with immunizations, to see their degree of impact on the reduction of respiratory morbidity. The analysis was performed for each age group.

Group 1 to 2 years old

In this age group, from the 58 children vaccinated against Hib, but not against *S. pneumoniae*, 46 did not show severe respiratory pathology (79.31%), while the remaining 12 children (20.68%) recorded hospitalizations, otitis and respiratory infections that required antibiotic treatments. There were no significant differences between the groups.

Regarding the 20 children vaccinated both Hib and antipneumococcic, 19 (95%) had no serious respiratory disease; there was only one case requiring medical care for severe respiratory tract illness.

Two unvaccinated children were also included in this age group; both of them had repetitive respiratory infections and hospitalizations requiring antibiotics until the time of the study (tab. IV).

TABLE IV

Distribution of children aged 1-2 years depending on immunizations and pathology

Pathology	Hib+ antipneumococcic+		Hib+ antipneumococcic-		Unvaccinated		p*
	G	B	G	B	G	B	
Total=80 children	**12**	**8**	**23**	**35**	**0**	**2**	**-**
ARI 6 children	1	0	2	2	0	1	0.250
Otitis 4 children	0	0	1	3	0	0	-
Hospitalized 5 children	0	0	2	2	0	1	0.276
No serious respiratory diseases 65 children	11	8	18	28	0	0	0.167
p*	0.304		0.864		-		

*Kruskal-Wallis test

Group 2 to 3 years old

Of the 37 children aged 2-3 years, who were vaccinated against Hib, but not against S. pneumoniae, 32 did not have severe respiratory pathology (86.48%) and 5 children (13.51%) have a higher susceptibility. Regarding the 25 children vaccinated both Hib and antipneumococcic, 22 (88%) did not have severe respiratory tract respiratory disorders (tab. V).

In this age group, there was only one child with all immunizations refused and which is evidenced by repeated otitis media.

The age group 3-4 years old

Of the 47 children 3-4 years old only vaccinated against Hib, 43 did not have severe respiratory pathology (91.48%), while of the 18 children vaccinated both Hib and Antipneumococcic, 15 (95%) were without respiratory problems (tab. VI).

Three children were denied immunizations, two of them registering until the time of study a number of repeated hospitalizations and otitis media.

The age group 4-5 years old

Of the 64 children vaccinated against Hib, 54 did not have severe respiratory pathology (84.37%), while 10 (90.90%) of the 11 Hib and antipneumococcic vaccinated children were without serious respiratory infections disease. There was no case of refusal of vaccinations at this age stage (tab. VII).

TABLE V

* Kruskal-Wallis test

Age group 5-6 years

Of the 51 children aged 5-6 years only vaccinated against Hib, 45 had no serious respiratory pathology (88.23%), and of the 9 children vaccinated with both Hib and antipneumococcic, 7 (77.77%) did not have had respiratory conditions requiring repeated antibiotic treatments. No cases of refusal of immunization have been reported in this age group (tab. VIII).

The distribution of 346 children according to respiratory pathology and vaccines showed that 83% of non-vaccinated children developed respiratory pathology, while this pathology was present in less than 15% of the vaccinated children (p=0.001) (tab. IX).

TABLE IX

Distribution of the batch 1-6 years depending on the immunizations and pathology presented

TOTAL 346 children	Hib+ antipneumococcic -	Hib+ antipneumococcic+	Unvaccinated
With respiratory pathology	37 (14.4%)	10 (12.0%)	5 (83.3%)
Without respiratory pathology	220 (85.6%)	73 (88.0%)	1 (16.7%)

DISCUSSION

In the context of strategies to lower infant mortality rates, control over respiratory diseases must occupy an important place. Strategies for the prevention of acute respiratory infections in young children include vaccination in the first place. To this, from the prenatal period, it needs to be added the careful monitoring of pregnancy in order to reduce prematurity and low birth weight, promoting natural nutrition, prevention and correct treatment of debilitating diseases (iron deficiency anemia, obstructive rickets, malnutrition, zinc deficiency) (4, 5).

Acute respiratory infections represent a complex and heterogeneous group of diseases caused by a large number of etiological agents and affecting any part of the respiratory tract (6). Worldwide, the WHO has proposed Global Immunization Vision and Strategy (GIVs) so that, through a joint effort, national immunization programs promote anti-Hib, pertussis, antipneumococcal vaccination, the ultimate target being the decrease of morbidity and mortality thought respiratory disease in children (7).

Hemophilus influenzae type b, known as Hib, is a gram-negative bacterium that causes severe infections and invasive diseases such as meningitis, pneumonia, epiglottitis, otitis, cellulitis, septic arthritis, in children younger than 5 years of age. The pathway of penetration of the pathogen is nasopharynx, and the source of infection is, in most cases, the healthy carrier. The newborn is contaminated by aspiration of contaminated amniotic fluid or by contact with Hib-infected vaginal secretions. It should be noted that 2/3 of the Hib invasive infection cases were found under 18 months, with a peak incidence of 6-11 months.

One of the risk factors for the occurrence of systemic disease is viral infection or Mycoplasma pneumoniae prior to illness. These pathogens are the main etiological agents of the pneumonia of children attending gardens. Therefore, in the absence of vaccination of infants from families where there are older children going to collectivities, the risk of Hib infection and the occurrence of invasive disease with all its complications is very high. Also, in the absence of vaccination, the complications of these diseases, represented alongside death by neuromotor retardation, deafness, seriously affect the child's health and the quality of life of the whole family (8, 9).

Currently, two vaccines which contain the Hib capsular polysaccharide conjugated to different proteins are available for use in

infants and young children. Regardless of the type of vaccine chosen, the effectiveness of anti-Hib vaccination in the prevention of invasive disease (especially meningitis and pneumonia) was greater than 90%. Epidemiological studies conducted in the United States in the 1980s, prior to vaccination, in children under the age of 5, showed that there were approximately 20.000 cases of Hib infection annually compared to the period 2003-2010 where the incidence of the disease decreased to an average of 398 cases per year (10). Subsequently, between 2010-2011, 33% of children under 5 years of age were diagnosed with Hib invasive disease, all under the age of 6 months, without the complete vaccination schedule. The cause of the vaccination failure is not exactly known, but it is associated with a number of factors related to the child's early childhood environment, school-age brothers, families with many members, low socio-economic status, low education and information parents. Host factors include: lack of natural nutrition, chronic diseases (immunodeficiencies, hemolytic anemia, oncological diseases-especially during chemo-therapy) and possibly sex (there is an increased risk for the male sex) (11,12).

In Romania, prior to the introduction of vaccination, 60% of the invasive Hib disease occurred in children before 12 months, reaching a peak at the age of 6-11 months. In 2010, 16 new cases of Hib infection were reported, and in 2011 other 5 cases (13).

Streptococcus pneumoniae (*S. pneumoniae*) is another major cause of morbidity in children, and is the cause of most bacterial pneumonia, otitis media, septicemia and purulent meningitis. Prior to the large-scale use of Prevenar in the United States, 17,000 cases of pneumococcal infections occurred every year in children under 5, causing about 200 deaths. Furthermore, *S. pneumoniae* continues to pose a real challenge also for the 21st century medicine, because antibiotic resistance has increased in most countries in recent years (14).

In Romania, the study by Falup-Pecurariu *et al.*, 2013, before the introduction of routine antipneumococcic vaccination into the national immunization scheme showed that in two hundred and twelve children with AOM, 99 (46.6%) episodes occurred in patients <12 months of age, 114 pathogens were recovered: *S. pneumoniae* was the most common isolate (81 isolates, 70.3% of all culture-positive episodes), followed by non-typing *Hemophilus influenzae* (26, 20.7%), *Streptococcus pyogenes* (5, 4.5%) and *Moraxella catarrhalis* (2, 1.8%). The most common S. pneumoniae serotypes were 19F (14, 29.2%), 6B (8, 16.7%), 23F (8, 16.7%), and 14 (6, 12.5%). Non-PCV13 serotypes represented six (12.6%) of all serotypes (four of them non-susceptible to penicillin). Thirty-six (75.0%) isolates were potentially covered by PCV7, 37 (77.0%) by PCV10, and 42 (87.5%) by PCV13. In these patients, multidrug resistance was found in 33 (68.7%) isolates (13).

In our study, we observed of the 340 children vaccinated against *Hemophilus influenzae* type b, 47 had severe respiratory pathology - 13.82% and frequently required antibiotics or were hospitalized.

Although the distribution of cases by sex, associated pathologies and the presence of immunizations did not show statistically significant differences in each age group, however these differences were present in the whole cohort, demonstrating the effectiveness of immunization in reducing respiratory and severe ENT pathology.

CONCLUSIONS

The most common causes of invasive disease (pneumonia, meningitis) at young age are infections with Streptococcus pneumoniae and *Hemophilus influenza*. In our study, we concluded that respiratory pathology was present in 83% of unvaccinated children and in less than 15% of vaccinated children. Vaccination, as a strategy for decreasing the infant mortality rate, is the main method of preventing respiratory diseases in infants and children.

PROFILUL CLINIC AL NODULILOR TIROIDIENI ÎN CLINICA DE ENDOCRINOLOGIE A SPITALULUI "SF. SPIRIDON" IAŞI ÎN PERIOADA 2005-2009

C. Buzduga, Voichiţa Mogoş, Corina Găleşanu, Carmen Vulpoi, Maria Christina Ungureanu, C. Cristea, Cristina Preda, E. Zbranca
Universitatea de Medicină şi Farmacie"Gr.T. Popa" Iaşi

Disciplina de Endocrinologie

CLINICAL PROFILE OF THYROID NODULES IN IAŞI, DEPARTMENT OF ENDOCRINOLOGY, ST. SPIRIDON HOSPITAL, BETWEEN 2005-2009 (Abstract): Thyroid nodules are common, with up to 50% of the adult population having palpable nodules. With the use of ultrasound, up to 10 times more nodules are likely to be detected. Given this we decided to evaluate by retrospective study the incidence of thyroid nodule in the North-Eastern Region of Romania (Moldavia) between 2005-2009. **Material and method**: We reviewed the records of patients admitted in the Department of Endocrinology, St. Spiridon Hospital Iaşi between 1.01.2005-31.12. 2009 (4712 patients) and with selected the cases with nodular goiter. **Results**: A total of 3105 cases of nodular goiter were identified. The women were most affected and highest prevalence was noticed for the patients with ages between 51-60 years. Most of the nodules were found in the right thyroidian lobe and the majority of the patients were euthyroid . The peak of incidence of nodular hyperthyroidism was different from that of diffuse hyperthyroidism. **Conclusions**: Thyroid nodules are the most common endocrine problem and the increasingly frequent detection of nonpalpable thyroid nodules in asymptomatic patients requires new approaches for their management. **Key words**: THYROID NODULE, INCIDENCE, ULTRASOUND

Nodulii tiroidieni reprezintă o patologie comună a glandei tiroide iar frecvenţa lor variază în funcţie de metoda de explorare aleasă. Astfel, prin palpare pot fi decelaţi la 4% -8% dintre adulţi, în timp ce prin evaluare ultrasonografică frecvenţa lor variază intre 13% -67%. La autopsie, aceştia au o incidenţă de aproximativ 50% (1,2).

Frecvenţa nodulilor tiroidieni creşte cu înaintarea în vârstă (3). De asemenea, există variaţii şi în funcţie de sex, femeile având de o prevalenţă mai mare decât bărbaţii.

Descoperirea clinică a unui nodul evocă întotdeauna posibilitatea unei tumori maligne, întrucât în 95% din cazuri cancerul tiroidian se prezintă sub această formă (4,5).

Patologia tiroidiană ocupă un loc important în afecţiunile endocrine din România şi, în special din Moldova, ca urmare a deficitului alimentar în iod şi a profilaxiei insuficiente (6).

OBIECTIVE

Studiul prezent şi-a propus evaluarea patologiei nodulare tiroidiene în Moldova , regiune caracterizată, anterior introducerii iodării universale a sării în 2004, drept o zonă cu un deficit moderat de iod, dar în acelaşi timp având şi un istoric particular din punct de vedere al expunerii populaţiei la radiaţiile ionizante (evenimentul de la Cernobîl din 26 aprilie 1986, când în urma

exploziei reactorului nuclear o cantitate mare de izotopi radioactivi, printre care şi I^{131}, au fost eliberată în mediu).

MATERIAL ŞI METODĂ

Studiul a fost retrospectiv, a vizat perioada 1.01.2005-31.12.2009 şi a cuprins cazuistica Clinicii de Endocrinologie din cadrul Spitalul Clinic Judeţean de Urgenţă "Sf. Spiridon" din Iaşi. Lotul de studiu a fost format din 3105 pacienţi, prezentând nodularizare tiroidiană. Criteriul de selecţie a pacienţilor a fost reprezentat de prezenţa la examenul clinic/ecografic a cel puţin unei formaţiuni nodulare în loja anterioară a gâtului.

Prelucrarea matematică a datelor experimentale

Datele au fost introduse într-un tabel de lucru în programul Excel, sortate şi filtrate după diferite criterii. Prezentarea datelor s-a realizat prin *reprezentări grafice de tip „coloană" şi „sectoriale".* Au fost determinate pentru parametrii cuantificabili din punct de vedere matematic următoarele valori caracteristice : valoarea medie, deviaţia standard a valorilor. Interpretarea datelor a fost realizată cu ajutorul programelor : *MS Excel* 2003, *SPSS 12.0.*

REZULTATE

În perioada menţionată, în Clinica de Endocrinologie Iaşi au fost internaţi 4712 pacienţi. Dintre aceştia 66% (3105 pacienţi) au prezentat guşi nodulare, restul de 34% (1607 pacienţi) prezentând alte afecţiuni endocrine. Din punct de vedere al incidenţei s-a constatat o creştere a frecvenţei odată cu înaintarea în vârstă, atingând un maxim în intervalul de vârstă 51-60 de ani, pentru ambele sexe, după care s-a înregistrat o scădere progresivă. Un număr de 384 de pacienţi au prezentat guşi micronodulare (diametru nodul sub un centimetru) diagnosticul fiind realizate doar pe baza ecografiei tiroidiene. Autoimunitatea tiroidiană a fost asociată cu boala nodulară tiroidiană într-un procent de 19% (579 de pacienţi). Din punct de vedere al prezentării clinice, majoritatea pacienţilor, 1834 (57%) au prezentat guşi uninodulare raportat la cei cu guşi multinodulare în număr de 1391 (43%). Raportat la lobul tiroidian stâng în lobul tiroidian drept s-a găsit o tendinţă crescută la nodularizare. Astfel din totalul pacienţilor cu guşi uninodulare 59% (1077 de pacienţi) au prezentat nodularizare în LTD în timp ce 41% (757 de pacienţi) au prezentat nodularizare în LTS. Raportat la sexe, femeile au avut o incidenţă mult crescută a patologiei tiroidiene nodulare raportată la bărbaţi. Din totalul pacienţilor luaţi în studiu 89% (2769 de pacienţi) a fost reprezentată de populaţia de sex feminin, în timp ce restul de 11% (338 de pacienţi) a fost reprezentată de populaţia de sex masculin.

Cea mai mare parte a nodulilor decelaţi nu au fost însoţiţi de o modificare a funcţiei tiroidiene. Astfel din totalul pacienţilor cuprinşi în studiu, 88% (2733 de pacienţi) au prezentat eutiroidie în timp ce 9% (284 de pacienţi) au prezentat hipertiroidie şi 3% (88 de pacienţi) au prezentat hipotiroidie. Din totalul pacienţilor cu hipertiroidie internaţi in perioada 2005-2009 (664 de pacienţi), guşile nodulare însoţite de hipertiroidie au reprezentat 42% din totalul hipiertiroidiilor dintre care cea mai mare parte, 33% (219 de pacienţi), au fost cauzate de adenoame toxice şi guşi multinodulare. Adenomul toxic şi guşa multinodulară toxică au prezentat un vârf din punct de vedere al vârstei diferit de cel al hipertiroidiilor difuze (neînsoţite de nodularizare). Astfel, pentru adenoamele toxice s-a decelat un vârf in jurul vârstei 51-60 de ani în timp ce pentru guşile multinodulare toxice peak-ul de vârsta a fost de 61-70 de ani, iar pentru hipertirodiile difuze vârsta cea mai afectată a fost situată între 41-50 de ani.

CONCLUZII

Boala nodulară tiroidiană reprezintă o problemă de interes major în practica medicală, atât datorită frecvenţei mari a nodulilor tiroidieni cât şi riscului de malignitate pentru o parte dintre noduli. Incidenţa bolii nodulare tiroidiene atinge un maxim în intervalul de vârstă 51-60 de ani pentru ambele sexe după care se înregistrează o scădere progresivă. Cea mai mare parte a nodulilor tiroidieni sunt însoţiţi de eutiroidie. Autoimunitatea este implicată într-o mare măsură în nodularizarea ţesutului tiroidian în prezentul studiu. Incidenţa nodulilor tiroidieni este mai mare la sexul feminin faţă de cel masculin. Incidenţa crescută a nodulilor tiroidieni la femei poate fi rezultatul faptului că terenul estrogenic este factor favorizant al procesului de nodularizare. Patologia nodulară tiroidiană îmbracă în Moldova forme polimorfe, majoritatea pacienţilor prezentând guşi uninodulare lobul tiroidian drept având o tendinţă crescută la nodularizare. Vârful de incidenţă al hipertiroidiilor nodulare este diferit de cel al hipertiroidiilor difuze.

CURRENT ASPECTS REGARDING THE RELEVANCE OF INFLAMMATION IN MAJOR DEPRESSIVE DISORDER (Abstract): The World Health Organization predicts that depression, which already affects about 10% of the population in the United States, will be the world's leading medical condition by 2030. The relationship between inflammation and depression has a bidirectional potential, but the underlying mechanisms are still less knowledgeable. In this way, the theory that argues that the inflammatory process is an etiologic factor in depression associated increased levels of inflammatory markers with decreased levels of serotonin, a neurotransmitter important in the pathogenesis of depression. An increase in serum levels of cytokines may lead to decreased availability of serotonin and other neurotransmitters, activation of the hypothalamic-pituitary-adrenal axis and increased oxidative stress in the brain. Depressive symptoms can cause a slight inflammatory response by triggering certain hormonal disorders in the HPA axis that leads to increased susceptibility to infections. Thus, inflammatory mechanisms may provide new paths for intervention and prevention of depressive affective disorders. Also, inflammation could explain the fairly widespread association of somatic-type diseases (such as cardiovascular disease) and diabetes, as well as mental disorders such as depression or schizophrenia. Cytokines have been shown to be related to many depression symptoms to a variety of the population. Examination of gene expression profiles provides insight into how altered gene activity is linked with exposure to stress. The expression of a gene may increase or decrease, and it represents the first step in the production of proteins that communicate changes in cell functions, including those that are involved in the immune systems' response to the inflammation. **Keywords**: DEPRESSION, INFLAMMATION, COMORBIDITIES, GENETICS.

Depression is one of the most common diagnoses in psychiatric practice, having a major impact on patient functionality. The World Health Organization predicts that depression, which already affects about 10 percent of the population in the United States, will be the world's leading medical condition by 2030 (1). Research on the major depressive disorder is in continuous growth, given the scale of the phenomenon and its consequences both socially and financially (2). Currently, it is estimated that treating depression involves higher costs than the treatment of hypertension combined with that of diabetes (3). Also, given the high rate of relapse and suicidal risks attached to depression, new treatments, and in-depth studies are of course

needed in this area of research (4). Depression has a major impact regardless of social status, profession or age, for example, in a study published in 2017 on a sample of 89 students from the faculty of medicine, a series of scales and tests were applied and it was shown that 20% of first-year faculty students had a moderate to severe depressive episode, and those most likely to develop this disorder are those with a melancholic personality.

Numerous studies have highlighted biological abnormalities in patients with affective disorders and the inflammatory hypothesis has been lately under discussions (5). In this way, the inflammatory hypothesis of depression states that major depressive disorder is also associated with the activation of the innate immune system, increased proinflammatory cytokines and acute phase proteins (6). In support of this hypothesis, numerous studies have detected significantly increased levels of inflammatory markers in patients diagnosed with depression, as compared to healthy controls, especially in the case of interleukin IL-6, IL-1b, tumor necrosis factor alpha and C-reactive protein (7).

Empirical data previously indicated that stress is associated with high levels of inflammatory markers, particularly C-reactive protein and TNF-alpha (6). Experimental studies have also shown that stressful life situations may directly stimulate the production of pro-inflammatory cytokines (8). Inflammation also presents a risk factor for the development of cardiovascular diseases, diabetes, and neoplasia (9), while depressive symptoms have also been associated with the presence of inflammation (10).

However, the underlying mechanisms are not fully known. Several physiological mechanisms have been proposed, including changes in clotting factors, genetic factors that increase the risk of having depressive symptoms, as well as cardiovascular diseases and changes in glucose metabolism.

It cannot be said with certainty if depression leads to inflammation or inflammation to depression. It is not yet known due to the combination of the two, and it may be a reciprocal relationship through a positive feedback mechanism.

The relationship between inflammation and depression has a bidirectional potential, but the underlying mechanisms are still less knowledgeable. In this way, the theory that argues that the inflammatory process is an etiologic factor in depression associated increased levels of inflammatory markers with decreased levels of serotonin, a neurotransmitter important in the pathogenesis of depression (11). On the other hand, the depression could lead to inflammation. Psychological stress activates the sympathetic nervous system and releases hormones that in turn initiate acute phase responses, generating inflammation (12).

The psychological stress commonly associated with depression increases the number of inflammatory cytokines in both laboratory mice and in humans (13). Inflammation in patients with major depressive disorder is often associated with resistance to antidepressant therapy and it is believed that anti-inflammatory medication can increase the effectiveness of antidepressants (14).

Thus, in a study by Raison and Miller, numerous genetic changes were identified in patients with major depressive disorder involved with the inflammatory system. In rodents, administration of inflammatory cytokines or lipopolysaccharide-type in-

flammatory stimulants causes depressive behaviors that can be reduced by antidepressants (15). In this way, specific inflammatory cytokines that have been identified as promoters of depressive-like behavior in rodents are IL-6, TNF-a, and IL-1b, as well as C-reactive protein (16).

The mechanisms underlying the pathophysiology involves monoamines and contemporary drug therapy for depression and psychosis (17). However, the heterogeneity in appearance, evolution and response to treatment suggests the presence of additional mechanisms (18). Several observations support that the communication between the immune system and the brain is mediated by cytokines and that they are involved in the pathogenesis of these disorders (19). Animal models suggest that systemic inflammatory cytokines, such as IL-6, can communicate with the brain. An increase in serum levels of cytokines may lead to decreased availability of serotonin and other neurotransmitters, activation of the hypothalamic-pituitary-adrenal axis and increased oxidative stress in the brain (20).

Depressive symptoms can cause a slight inflammatory response by triggering certain hormonal disorders in the HPA axis that leads to increased susceptibility to infections (11).

Mechanistically speaking, chronic stress can trigger changes in the hypothalamic-pituitary-adrenal (HPA) axis and in the immune system, which in turn can trigger anxiety and depression (21). These paths are not independent because the HPA axis and the immune system are closely linked. While the HPA axis should normally moderate inflammatory reactions, its prolonged hyperactivity leads to abnormal anti-inflammatory responses that increase the inflammation. Also, hippocampal glucocorticoid receptors are inhibited by chronic neuroinflammation which exacerbates pro-inflammatory cytokine activity and aggravates chronic neuroinflammation. On the other hand, neuroinflammation causes an imbalance between oxidative stress and the anti-oxidant system, which is also associated with depression (22). It can also be hypothesized that the immunological changes associated with chronic diseases and aging could induce similar effects (23).

Since the HPA axis is regarded as the final common path for most depressive symptoms, recent studies have generated new hypotheses for the biological mechanisms of depression (24). For example, many studies have focused on cytokine-cytokine receptor interaction in the case of the inflammatory path. A meta-analysis comprising 24 studies that considered the measurement of serum cytokines in patients with major depressive disorder reported they had significantly higher concentrations of TNF-alpha and IL-6 (25).

Oxytocin, together with vasopressin, melatonin, insulin and other neuropeptides may influence mood and psychosocial functions. In a 2018-year study, for 8 days, oxytocin was injected intraperitoneally into adult mice, observing that compared to the control group, they experienced increased mood levels and reduced their stress and anxiety (26). Another study, referring to the implications of oxytocin in the mechanisms of mixed anxiety and depressive disorders, shows by a novel approach that intraperitoneal oxytocin injection for 9 days in a rat that was injected for 2 weeks with methionine revealed that levels anxiety, depression and stress have declined considerably (26).

Thus, inflammation is a physiological mechanism often mentioned in connection with the presence of depressive symptoms in the development of cardiovascular diseases (27).

Thus, inflammatory mechanisms may provide new paths for intervention and prevention of depressive affective disorders. Also, inflammation could explain the fairly widespread association of somatic-type diseases (such as cardiovascular disease) and diabetes, as well as mental disorders such as depression or schizophrenia (28).

In this way, we can state that the presence of depressive symptoms is not only a prognostic factor for patient with cardiovascular diseases but is also a risk factor for cardiovascular disease incidence in the case of healthy individuals (29).

During this time, the inflammatory response contributes to myocardial infarction by creating an instability at the atherosclerotic plaques level, which precipitates them to rupture or crack and leads to the formation of occlusive thrombus. This cascade of events could explain the high rate of morbidity and mortality in patients with myocardial infarction and associated depressive elements (30).

Cardiopathy represents a chronic inflammatory process involving an immune response to an injury on the vascular endothelium level (29). Moreover, in these patients, high levels of inflammatory markers (CRP, IL-6, and TNF-alpha) have been associated with increased cardiovascular events (31).

In this way, prospective epidemiological studies found that increased levels of inflammatory cytokines are a predictor for possible future cardiovascular disease in the initially healthy population. In addition, studies carried out on patients with depression, with or without cardiovascular disease, have found that the presence of depressive symptoms is associated with increased levels of inflammatory cytokines such as CRP, IL-6, IL-1 and TNF-alpha and that the associated antidepressant therapy appears to decrease the intensity of the inflammation (32).

Thus, the purpose of a study by Shang and his colleagues was to test the hypothesis that patients who suffered a heart attack also showed inflammation, indicated by elevated levels of inflammatory markers. A total of 280 patients were approached and 202 gave informed consent and completed baseline interview. 150 patients (77 females and 73 males with a mean age of 62,8 years old) were enrolled in the study and 75 met the criteria for major depression and heart attack and 75 served as control. They excluded patients suffering from chronic inflammatory diseases, other psychiatric pathology or a history of heart attack and the ones that were older than 80 and also the patient who refused to permit a blood sample to be drawn. Depression was evaluated using the BDI-II score (Beck depressive symptoms Inventory-II). Of the 77 females, 62.7% were depressed, while only 37.3% of the 73 males were depressed. Patients with depressive symptoms had significantly higher levels of TNF-α ($t = 2.070$, $p < 0.05$) compared with control group. Regarding CRP, IL-1β, and IL-6 levels no differences were found between the depressed and control participants. In conclusion, the results of the study demonstrated that patients with depressive symptoms had significantly higher levels of TNF-alfa in comparison with the control group (29).

Numerous studies have linked systemic inflammatory markers (IL-6, IL-1b, and CRP) with the risk of developing heart disease and diabetes, common comorbidities in depression and psychosis. A prospective study conducted by Golam and his colleagues came to support the hypothesis that high levels of IL-6 and CRP in childhood increases the risk of subsequently developing depression or psychosis (28).

Depressive and anxiety disorders are a category of psychiatric disorders with increased prevalence. There is much evidence that connects anxiety and cardiovascular risk factors such as atherosclerosis, metabolic syndrome, and coronary artery disease (33). Given that some degree of systemic inflammation is certainly involved in the etiology of these diseases, it was hypothesized that inflammation plays a role in the anxious-depressive pathology and may represent the link between anxiety and cardiovascular disorders (34).

Anxiety disorder is often associated with depression, which can be a sign of an immune function disorder. However, unlike with depression, very few studies have investigated the relationship between anxiety and inflammation (35). Recent studies have correlated anxiety with increased levels of cytokines and especially of C-reactive protein (36). In a study coordinated by Liukkonen the general population-based Northern Finland 1966 Birth Cohort was followed until age 31 (n=2,688 males and 2,837 females), when the highly sensitive CRP concentrations were measured. Anxiety and depressive symptoms were defined by Hopkins Symptom Checklist (37). After adjusting for confounders, logistic regression analyses showed that anxiety symptoms alone increased the probability for elevated CRP levels in men. Regarding anxiety disorders, research was primarily focused on post-traumatic stress disorder and increased levels of inflammatory markers were found (38).

Major Depressive Disorder, PTSD, and insomnia are associated with increased levels of inflammatory biomarkers as well as an increased risk of inflammatory comorbidities, such as metabolic syndrome, heart disease, obesity, and type 2 diabetes. (39) Chronic Insomnia, depression, and PTSD are associated with an increase in levels of inflammatory cytokines and C-reactive protein (40).

Depression is often correlated with suicidal behavior and there is now ample evidence that indicates that inflammation is associated with the severity of the depression since inflammatory molecules are increased in the blood and in the brains of depressive patients (post-mortem) (41).

For example, Mui *et al.* studied this issue in the case of US ethnic sub-groups and concluded that there is a greater association between the high degree of depression and level of inflammation in elderly Chinese immigrants, as compared to the older people of other ethnicities, and proposed further analysis that considers the stress caused by cultural shifts (42).

Another study by the Vogelzang group also followed the association between antidepressant medication and the characteristics of depressive disorders with the inflammation in a cohort of patients diagnosed with depression and a control group. It has been found that depressed men had elevated levels of CRP and IL-6, but not TNF-alpha. No associations of this type were found in women. A high level of inflammation was found in men that were

older at the onset of depression (CRP, TNF-alpha). Men with SNRI and TCA treatment had increased levels of CRP and IL-6, whereas patients with SSRI treatment had significantly lower values of IL-6. In conclusion, this study suggests a real correlation between depression and inflammation in men (43).

Regarding the genetical mechanisms behind this interaction, changes in gene expression lead to different protein activity in general. There are many mechanisms that help regulate protein production and availability, including epigenetic changes (37). Therefore, modifications of gene expression are one of the first investigations that may explain the molecular mechanisms that are related to changes in protein activities and offer new insights into the complex relationships between gene regulatory mechanisms.

Examination of gene expression profiles provides insight into how altered gene activity is linked with exposure to stress. The expression of a gene may increase or decrease, and it represents the first step in the production of proteins that communicate changes in cell functions, including those that are involved in the immune systems' response to the inflammation (44). Elements that disturb the balance of the body, such as physical and mental trauma, are correlated with increased concentrations of inflammatory proteins, which are most often the result of changes in gene expression. (37)

Epidemiological studies have linked infectious and autoimmune status of childhood psychosis to depression in adult life (45). Current antipsychotic and antidepressive treatments also have anti-inflammatory properties. A meta-analysis that involved increased cross-sectional studies have been reported and they had identified an increase in the serum levels of IL-6 and CRP in depression, first psychotic episode and recurrent acute psychotic disorders (46).

Also, The Avon Longitudinal Study of Parents and Children is a prospective cohort study which investigated the serum levels of IL-6 and CRP in children aged 9 years old and the risk of depression or psychosis at 18 years old. It was anticipated that the higher the initial values of IL-6 and CRP, the greater was the risk of developing depression or psychotic-type disorder. The study involved 4,500 children in England, and, at the end of the study, the initial hypothesis was confirmed (45).

Cytokines have been shown to be related to many depression symptoms to a variety of the population. For example, the allele of the rs IL4 2243248 gene has been associated with a high occurrence of depression in oncology (47), and polymorphisms of TNF-308 and IL6-174 were associated with fatigue and symptoms of depression in patients diagnosed with breast cancer (48). Also, IL-10 polymorphisms have been associated with depressive symptoms in patients with general infections or those with chronic kidney disease in the terminal stage (49). A high level of expression of the CXCL 11 gene (a gene that encodes cytokines) was identified in the case of a significant number of patients with Marfan syndrome and a low quality of life level (50).

Given that numerous genes likely to be involved in the mechanisms of depression were identified, but the results were not conclusive, Kao and his colleagues investigated this issue by reviewing the available data. 5055 genes were studied of whom 160

were identified as having an increased risk to be associated with depression. The first 7 genes are beta hydroxylase dopamine (DBH), the serotonin transporter SLC6A4, brain-derived neurotrophic factor (BDNF), nerve growth factor receptor (NGFR), tumor necrosis factor, glycogen synthase kinase 3 beta and the subunit gene that encodes the CHRNA7 receptor. Two of these genes support the theory of neurotransmitters. DBH dopamine catalyzes the biosynthesis of noradrenaline. A low DBH activity is a factor associated with depression. SLC6A4, belonging to serotonergic synapse pathways, is often associated with depressive symptoms. The neurotrophin signaling path is supported by the top 3 genes. BDNF is a neuroprotective protein that modifies the balance of neuroprotective and neurotoxic responses to stress. GSK3B is an enzyme involved in cell growth and neuronal energy metabolism and plays a key role in stabilizing the mood. NGRF modulates the activity of tyrosine-kinases for the neurotrophins family and may have a protective effect against developing depression. Kao and his collaborators concluded that neurotransmitters and the theory of neuroplasticity have the most evidence of association with depression (51).

Depression is a psychiatric disorder with a major impact on the patient's functionality, with implications in both the psychic sphere in the somatic one. Inflammatory hypothesis in depression is a current active topic, being supported by numerous studies and it represents a starting point for future research.

RISK FACTORS FOR COLORECTAL POLYPS: FINDINGS FROM A GREEK CASE--CONTROL STUDY (Abstract): There is a body of evidence showing that several lifestyle and dietary factors are associated with colorectal polyps' formation; however, the magnitude of this association in diverse populations remains unclear. The aim of this study was to investigate this association in a Greek sample. **Material and method**: The study comprised of 52 subjects with histologically confirmed advanced colorectal polyps and 52 healthy controls. Data concerning lifestyle and dietary factors were collected using a validated questionnaire. Logistic regression analysis was used to estimate odds ratios and 95% confidence intervals after adjustment for potential confounders. **Results**: Physical activity level (95% CI 0.032-0.953, P=0.044) and consumption of yoghurt (95% CI 0.969-0.996, P=0.024), cheese (95% CI 0.932-0.996, P=0.030), fish (95% CI 0.782-0.964, P=0.008), vegetables (95% CI 0.965-0.998, P=0.029), and garlic (95% CI 0.005-0.671, P=0.022) were inversely associated with colorectal polyps. Increasing age (95% CI 1.005-1.231, P=0.039) and central obesity (95% CI 1.001-1.019, P=0.025) were strongly associated with their presence. **Conclusion**: Our study indicates that a cluster of modifiable risk factors have significant impact on colorectal polyps' occurrence in Greek population. **Key words**: CASE-CONTROL STUDY, COLORECTAL POLYPS, DIET

It is well known that the prevalence of colorectal polyps (CRPs) varies among different ethnic and/or geographic regions. In average, their incidence among asymptomatic individuals ranges from 10% in sigmoidoscopic to 25% in colonoscopic studies. The possibility to find new polyps three years after an initial negative endoscopy seems to range from 7% in sigmoidoscopic to 27% in colonoscopic studies (1). Furthermore, the findings of a recently published study suggest that advanced colorectal adenomas' prevalence is 7% (2). What should be stressed at this point is that the incidence might be higher than estimated due to the fact that the so-called "flat colorectal adenomas" may, sometimes, not be recognized. What should also be taken into consideration is the fact that flat adenomas' prevalence could even exceed 10% of the total number of polyps found at colonoscopy (3). Recently developed methods, like chromoendoscopy, seem to considerably increase the detection rate (4).

CRPs are considered the most important precancerous lesions and it is important to note that hyperplastic and adenomatous polyps share many risk factors with each other as

well as with colorectal cancer (5). However, more likely to develop into colorectal cancer are advanced adenomas, which are either classified as ≥1cm in size or present ≥25% villous histology or exhibit high-grade dysplasia compared to smaller ones. Due to this, it is of great importance to try to reduce the formation of advanced CRPs and, of course, to remove them at the time of their discovery during colonoscopy.

Research on diet and CRPs has already focused on specific foods or nutrient components, such as fat (6,7,8,9,10,11), meat (12,13), dietary fiber (14,15,16), vitamins (17,18,19,20,21,22,23,24), fruits and vegetables (25,26,27,28) and dairy products (29,30). Furthermore, some research concerning the effect of smoking habits, alcohol consumption (31,32,33), obesity and physical activity (32,33,34,35,36,37,38,39,40,41,42) on CRPs' formation has also been carried out. So far, the findings of these studies remain either unclear or inconsistent.

Despite the fact that a large number of studies have investigated the role of dietary habits, physical activity level and certain anthropometric characteristics on colorectal carcinogenesis, a relatively small number of studies have examined simultaneously the association between the same variables and the presence of CRPs. Furthermore, it should be noted that in their majority these studies examine this association independently of CRPs' size. The present study was specifically designed to investigate the effect of anthropometric characteristics and lifestyle factors, such as dietary habits, smoking, alcohol consumption and physical activity level on CRPs' formation in a cohort of Greek patients with advanced CRPs (as, to our knowledge, no other study has examined this association in a Greek population).

PATIENTS AND METHODS

The study population consisted of 52 cases (32 males, 20 females), aged 30-77 years, with histologically confirmed advanced (diameter >1cm) CRPs, who underwent full colonoscopy at Gastroenterology Department of Saint Panteleimon Hospital, Greece during the period from January 2008 to June 2009. An equal number of healthy subjects matched for age (±3 years) and sex were used as controls. The latter were participants of a colorectal cancer screening program held by the same Department of the same Hospital and had also underwent full colonoscopy during the same period. In more details, 52 subjects with negative colonoscopy, of the similar distribution by sex (32 males, 20 females) and age (range 33-80, mean age of controls vs cases: 60±11 vs 57±10.5 years, $P=0.11$), served as controls. At this point, it is worthy to mention that in the present study cases and controls were matched one to one.

Data were collected through a face-to-face interview guided by a standardized questionnaire and each interview lasted approximately 60 min. The questionnaire included information on socio-demographic characteristics and lifestyle habits, such as smoking habits and physical activity level.

In order to assess physical activity level, a questionnaire based on the validated Cambridge Physical Activity Index, as described by Wareham et al. (43), was used. According to this, subjects were asked about the type of their occupation (sedentary, standing, manual or heavy manual) as well as the time they used to spend weekly physically active during their leisure time (no time, 3.5 hours or less per week, from 3.5 to 7.0 hours per week). After answering these questions, subjects' physical activity was divided into three levels. In level 1 were inactive subjects (those with sedentary work and with no time spent at physical activity during leisure time). In level 2 were moderately active subjects (those with sedentary work who spent 3.5 hours or less per week physically active as well as those with standing

TABLE I
Differences in the distribution of potentially risk factors for CRPs between cases and controls (results of univariate analysis)

Variables	Cases (n=52)	Controls (n=52)	P-value
Smoking (Yes)	34.6	30.8	0.676
Physical activity			
Level 1	61.5	34.6	0.006

Data are mean (SD) and percent for continuous and categorical variables, respectively

work who spent no time at physical activity during leisure time). Finally, in level 3 were active subjects (those with sedentary work who spent from 3.5 to 7.0 hours per week of their leisure time physically active, those with standing work who spent 3.5 hours or less per week of their leisure time physically active, as well as those with manual and heavy manual work – independent of the time they used to spend per week at physical activity during their leisure time) (44).

A medical history was also recorded and participants were classified as presenting hypercholesterolemia if a doctor had told them that blood cholesterol was high, before being prescribed or not a cholesterol-lowering drug.

Height and weight were measured in all case and control subjects by using standard procedures. In particular, body weight was measured by the researchers to the nearest of 0.1Kg and in light clothes, while height was also measured in standing position. Body Mass Index (BMI, in Kg/m^2) was calculated as weight in kilograms divided by height in meters squared. A body fat analyzer (BF 902, OMRON) was used in order to determine body composition by measuring bioelectrical impedance. At this point, it should be mentioned that this method of estimating body composition is based on the ability of the tissues to conduct an electric current and is generally thought to be a good pre-

dictor of body fat, especially when it comes to epidemiologic studies (45,46). Finally, subjects' central obesity was estimated by measuring waist circumference (in cm) while they were in a standing position.

Finally, in order to assess subjects' habitual diet, a validated Food Frequency Questionnaire (FFQ) was used (47). The latter consisted of 79 questions and was used to assess the average daily frequency of consumption of specific foods during the 2 years prior to the survey. In more details, with its use it was able to estimate each subject's average daily consumption of milk, yoghurt, yellow and white cheese, margarine, butter, cream, mayonnaise, oranges, apples, pears, tangerines, peaches, apricots, bananas, melon, watermelon, grapes, strawberries, cherries, broccoli, cauliflower, cabbage, carrots, corn, lettuce, spinach, pea, lentils, beans, tomatoes, poultry, processed meat, veal, lamb, pork, fish, seafood, eggs, bread, cereals, biscuits, cakes, chocolate, potatoes, rice, spaghetti, nuts and seeds, coffee, tea, alcohol, sugar and honey. The supplementary use of nutrients, the type of fat used in the preparation of the food, as well as the consumption of organic foods was also investigated.

STATISTICAL ANALYSIS

Pearson chi-squared statistics and t-tests were used to evaluate case-control differences in the distribution of potentially confounding factors. Odds ratios (ORs) were used to measure the association of CRPs' presence with risk factors. Logistic regression analysis was used to estimate ORs and 95% confidence intervals (CIs), after adjustment for potential confounders. Variables that were statistically associated in the univariate analysis were included in the analysis. Furthermore, risk factors identified previously (including age, sex, nutritional status and smoking) as having an independent association with CRPs were controlled in the logistic regression model. A P value <0.05 was considered statistically significant and all statistical tests were based on two-sided probabilities using SPSS, version 16.0.

RESULTS

Univariate analysis

As shown in table I statistically significant differences between cases and controls were found for physical activity level, alcohol, fish, yoghurt, cheese, red meat, vegetables and garlic consumption. Furthermore, it should be mentioned that marginally significant differences were found concerning waist circumference. One interesting finding of the present study concerns the effect of hypercholesterolemia on CRPs' development. In more details, the presence of hypercholesterolemia was found to be significantly associated with higher percentage of CRPs. Finally, no significant differences between cases and controls were found concerning smoking habits as well as consumption of water and other foods such as milk, eggs, poultry and legumes.

Multivariate analysis

After performing multivariate analysis it was found that physical activity and consumption of yoghurt, cheese, fish, vegetables, and garlic were negatively associated with CRPs (table II). On the other hand, age and waist circumference were found to be positively associated with CRPs. Finally, a trend for significant difference on alcohol consumption between cases and controls was also found, but the difference did not actually reach statistical significance (OR= 1.006, 95% CI 1.000-1.013, $P=0.066$).

DISCUSSION

This case-control study examined the possible associations between lifestyle and dietary factors and CRPs, which are thought to be precursors of colorectal cancer. It was conducted in a sample of Greek population, which ranked among the populations with

TABLE II
Factors significantly associated with presence of colorectal polyps (results of multivariate analysis)

Risk factor	Odds ratio†	95% Confidence Intervals	P-value
Age	1.11	1.005-1.231	0.039

** Reference group*

the lowest colorectal cancer incidence in Europe (48). It has been hypothesized that the latter observation is attributed to the protective effect exerted by favorable combinations of the Mediterranean diet's components, which is generally characterized by frequent consumption of fruits, vegetables, pulses and fish, moderate consumption of milk and dairy products and low consumption of meat and cheese, while one of the Mediterranean's diet major characteristics is the almost exclusive use of olive oil as seasoning (49).

The findings of the present study suggest that yoghurt and cheese consumption seems to exert a significant protective action against CRPs, which is thought to be due to their high content in Ca. This hypothesis is supported by the finding of a recent study, according to which supplementary intake of 1000-2000mg of Ca daily seemed to reduce adenoma recurrence (29). However, dairy products' high content in Ca might not be the sole underlying mechanism of the observed association, as they are rich sources of other potential chemopreventive agents, such as vitamin D, sphingolipids, conjugated linoleic acid, butyric acid and probiotic bacteria. In fact, the findings of a previous trial cohort suggest that Ca and vitamin D intakes may be inversely associated with adenoma recurrence risk (22).

One interesting finding of the present study was the one concerning hypercholesterolemia. As the univariate analysis showed, the presence of hypercholesterolemia was found to be associated with increased CRPs' risk, but the association was not confirmed after performing multivariate analysis. This might be due to the possible interaction between the presence of hypercholesterolemia and yoghurt and cheese consumption. Therefore, this finding highlights the need that, in clinical practice, patients should be advised to consume dairy products as part of a balanced diet.

We also found an inverse association between garlic consumption and CRPs, which remained statistically significant after adjusting for other dietary factors. To our knowledge, few studies have investigated the association between garlic consumption and CRPs' risk (50,51,52). Garlic contains components such as diallyl sulphide and allyl methyl trisulfide that might be responsible for the observed protective effect of garlic consumption against carcinogenesis. In particular, garlic's sulphur components have been reported to suppress experimentally induced tumor incidence in several organs, including the colon. In preclinical studies, both water- and lipid-soluble allyl

sulfur compounds arising from processed garlic inhibited aberrant crypt foci, which are proposed to be early preneoplastic lesions of adenoma-carcinoma in humans (53).

The protective effect of fish consumption on CRPs' development has also been observed in a previous quantitative review of eleven case-control and two cohort studies (30). Moreover, it has been found that higher fish consumption seems to be associated with lower risk of adenoma recurrence (13). This favorable effect of fish consumption is thought to be due to its high content in n-3 fatty acids, which have been found to reduce the progression of small adenomas to large ones (10). Moreover, when trying to identify the plausible mechanisms of the observed association, it should seriously be taken into consideration the fact that fishes are rich sources of selenium, as it has already been found that higher selenium levels seem to be associated with decreased risk of both colorectal adenoma and colorectal cancer (24).

A similar association has also been found concerning vegetables. More specifically, vegetables consumption seems to protect against CRPs. The findings of previous studies that have examined the association between vegetables intake and the risk of CRPs' development remain equivocal. However, the risk estimates have, generally, been in the protective direction (25,27,28). When trying to explain the findings of these studies, it should seriously be taken into consideration that it is a very complex group, involving food items that might exert protective action, others that could exert this action to a lesser extent, while there might also be vegetables that do not protect against CRPs at all. So, it might be a good idea to examine those foods in particular and not as a whole.

In the present study waist circumference was an independent risk factor, as it was found to be significantly associated with CRPs' occurrence. The finding supports the findings of previous studies (36,37,38). Moreover, it has already been proposed that obesity, especially central obesity, could also be viewed as a promoting factor in colorectal adenomas' growth as well as that it could increase colorectal cancer risk (37, 38,54). Finally, at this point it is important to mention that obesity has been related to colorectal cancer through its association with elevated insulin and glucose levels (41). However, the underlying mechanisms of the observed association remain unclear.

Finally, in our study, increased physical activity was found to protect against advanced CRPs' formation in the Greek population studied. Since advanced CRPs are thought to be precancerous lesions, it should be mentioned that the underlying biological mechanisms of the observed association could be similar to the ones explaining the association that has consistently been found between physical activity and colorectal cancer. In more details, sedentary lifestyle has generally been associated with hyperinsulinaemia, since both the insulin-like growth factor family and insulin have been associated with enhanced tumor growth and antiapoptosis. Individuals with higher circulating levels of insulin, its secretion's marker, C-peptide and inslulin-like growth factor-1 seem to be at increased risk for colon cancer (55). Apart from that, it has been proposed that increased physical activity protects against colorectal cancer by helping to maintain the energy balance and, thus, to maintain a healthy body weight, as well as by enhancing the immune system (56,57). Furthermore, increased physical activity is associated with increased gut motility, which leads to decreased gastrointestinal transit time and, thus, decreased exposure of the intestine mucosa to carcinogens. Finally, increased physical activity leads to a favorable ratio of prostaglandins, as it seems to

increase prostaglandin F, which increases gut motility and inhibits colonic cell proliferation, while, at the same time, it does not increase prostaglandin E2, which affects colonic cell proliferation opposite to the way that prostaglandin F does (58).

CONCLUSION

Our findings confirm that yoghurt, cheese, fish, vegetables and garlic consumption provides protection against advanced CRPs' formation. The same protection seems to be provided by increased physical activity. On the other hand, age and central obesity were found to be independent aggravating factors, as they significantly increased CRPs' development risk. Our findings also support the hypothesis that some of the environmental and nutritional factors involved in colorectal carcinogenesis are also involved in the genesis of colorectal polyps in Greek population.

NEURO-PSYCHIATRIC ONSET OF GRAVES' DISEASE IN CHILDREN. CASE REPORT AND LITERATURE REVIEW (Abstract): Children with thyrotoxicosis are usually hyperactive with behavioral problems, difficulty in concentration and attention. Neuropsychiatric disturbances in children with Graves' disease (GD) can be mistaken for "true" psychiatric or neurologic disorder delaying the diagnosis and the correct therapeutic approach. We present the case of an 8 years old with important height and weight gain in the last two years. The patient had a medical history of ADHD. Despite the psychotherapy the behavior has not improved. Physical examination revealed increased weight and height, exophthalmia and lid retraction, diffuse goiter, important tremor, hyper talkativeness, warm and moist palms and tachycardia. The diagnosis of GD was confirmed by the values of thyroid hormones and the presence in high titers of thyroid stimulating hormone receptor antibodies (TRAb). After several months of treatment with ATDs only, we have switched "on block and replace" therapy. During the 3 years surveillance, the height and weight velocity rates remained increased with an advanced bone age. Once euthyroidism achieved and maintained, also the neuropsychiatric abnormalities, including irritability, anxiety, sleep disturbances and mood changes improved. The school performances improve to, and the inability to concentrate disappeared after several months. At the moment the patient is still on a minimal dose of ATD with normal hormonal levels. Neuro-psychiatric manifestations can be the first sign of thyrotoxicosis in children and adolescents. A close collaboration with parents is required in order to have the desired results: euthyroidism and disappearance of neuropsychiatric dysfunctions. **Keywords**: THYROTOXICOSIS, CHILDREN, MOOD DISORDERS, HYPERACTIVITY.

Thyroid dysfunction may cause, or be associated with, a wide range of psychiatric and or neurological disorders in children and adolescents. Graves' disease (GD) is the most common cause of thyrotoxicosis in pediatric population with a prevalence of 1 in 10,000 children (1). GD account for 10-15% of childhood thyroid diseases and its incidence rises from 0.1/100,000 in young children to 3/100,000 in adolescents (2). GD is more common in girls than in boys (3). The classic clinical picture includes diffuse goiter, exophthalmia, increase appetite, weight loss, palpitations, excessive physical activity, nervousness, thermo phobia, tremor, accelerated linear growth (1). Children with thyrotoxicosis are usually hyperactive with behavioral problems such as: difficulty in concentration and attention, disturbances which may lead to decreased cognitive performance (4).

Neuro-psychiatric disturbances in pediatric GD are rare and can be mistaken for "true" psychiatric or neurologic disorder delaying the diagnosis and so, the correct therapeutic approach. Hyperthyroidism can present as a hypomania or maniac-like state, anxiety, depression, mixed mood disorders, emotional lability and irritability (5). It is believed that hyperthyroidism affect the activities of neurotransmitters (serotonin and dopamine) in the central nervous system and possibly account for the neuropsychiatric abnormalities. Thyroid hormones are responsible for the modulation of the beta-adrenergic response to catecholamines in the central nervous system and so, may contribute to psychotic behaviors in thyrotoxic patients (6). GD is associated with, or may cause, a spectrum of central and/or peripheral neurological dysfunction and a considerable variation in clinical phenotype is described (7). There is a connection between the effects of thyroid hormones and several frequent psychiatric disorders. Minor changes in thyroid hormone concentrations, may have important effects on cerebral function. This may manifest as alterations in mood, behavior and cognition (8).

The diagnostic of GD may be very challenging in children due to clinical manifestations which may mimic a neuropsychiatric disorder. It takes sometimes a long period of time until the positive diagnosis of GD is done. This will interfere with growth and development of the child and also may lead to serious cardio-vascular complications. Here we report a girl with GD who was initially diagnosed with attention deficit hyperactivity disorder (ADHD) due to important cognitive deterioration, difficulties with attention and hyperactivity.

CASE REPORT

We present the case of an 8 years old girl admitted in our department for important height and weight gain in the last two years. The patient had 18 months history of increasing irritability, insomnia, mood swings, and impaired concentration. Her mother said that she become unfriendly with colleagues at school and the anxiety, nervousness, restlessness, diminished concentration and hyperkinesia lead to her poor school performance. Due to difficulties with concentration and attention and hyperactivity she was diagnosed with ADHD and underwent psychological counseling. Despite the psychotherapy the behavior has not improved. Moreover, she has developed an uncontrolled appetite which leads to a rapid increase in weight.

Physical examination revealed increased weight and height (both at +2 SD), exophthalmia and lid retraction (fig. 1). At palpation thyroid was soft, diffuse enlarged, smooth, and non-tender (fig.1). The patient presented hyperkinesia, important tremor, hyper talkativeness, warm and moist palms, tachycardia (110 beats/minute) and normal blood pressure.

The thyroid ultrasound examination revealed a 40 mL thyroid volume (normal value according WHO (9) for age and sex is 6.9 mL), intense hypoechogenic structure and an increased vascularization in Doppler mode (fig. 2).

Fig. 1. Lid retraction and diffuse goiter at clinical examination.

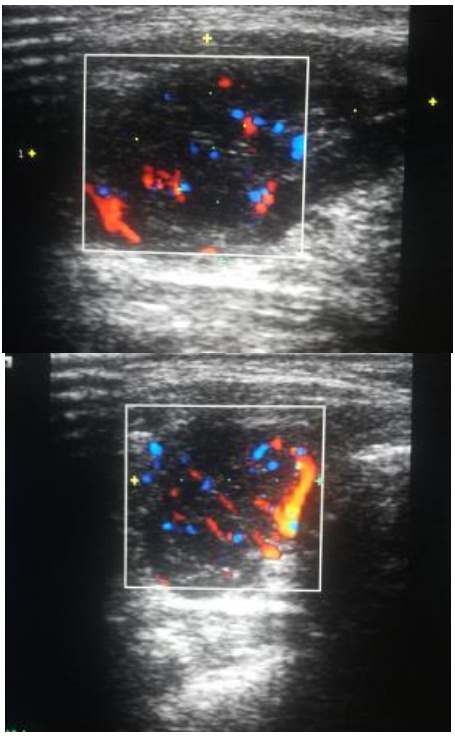

Fig. 2. Thyroid with increased volume, important hypoechogenic structure and increased vascularization on neck ultrasound.

All these data were specific for autoimmune thyroid disorder. The hormonal profile was in accordance with the clinical picture of hyperthyroidism (thyrotoxicosis): TSH (thyroid stimulating hormone) = 0.022 µIU/mL (normal values 0.35-5.6), fT4 (free thyroxin) = 1.44 ng/dL (normal values 0.89-1.76), fT3 (free triiodothyronine) =10.5 pg/mL (normal values 2.4-8.6). The presence in high titers of antithyroid antibodies: anti-peroxidase (TPOAb) > 1,000 IU/mL (normal values 0-35) and anti-thyroglobulin (TGAb) > 3,000 IU/mL (normal values 0-40) was also recorded. Considering the presence of thyrotoxicosis with ophthalmopathy, suggestive for GD, we have measured the level of thyroid stimulating hormone receptor antibodies (TRAb) which showed very high values 37.4 UI/L (positive> 1.5).

The treatment was started with antithyroid drug (ATD) Thiamazole 15 mg/day with caution for side effects such as: agranulocytosis, thrombocytopenia, hepatitis, skin rash, and urticaria. Also, a ß blocker (propranolol) was added in order to manage the tachycardia and also to improve the metabolism of T4 in T3 at cellular level.

After two months the patient was retested for thyroid function and the physical examination was performed. The girl's mother said that it was very difficult for her to persuade her daughter to take the medication. Indeed, the hormonal picture was slightly improved (TSH still low, fT4 normal and fT3 8.9 *vs.* 10.5 pg/mL (before ATD). The tremor was present, blood pressure was normal and heart rate= 90 beats/minute. The patient was seen every 3 months for a period of 3 years. This strict follow-up was necessary due to unpredictable evolution with ATD treatment (tab. I).

It was very difficult to set a dosage able to achieve euthyroidism. Even slight increase or decrease in daily dosage of Thiamazole (according with fT4 and fT3) were succeeded by important variations of TSH, fT4 and fT3 values. After several months of treatment with ATD only, we have switched "on block and replace" therapy (high dose of ATD with levothyroxine in order to achieve euthyroidism). During the 3 years surveillance, the height and weight velocity rates remained increased with an advanced bone age. Once euthyroidism achieved and maintained, also the neuropsychiatric abnormalities, including irritability, anxiety, sleep disturbances and mood changes improved. The school performances improve to, and the inability to concentrate (major complain at the first visit) disappeared after several months. Regarding the ophthalmopathy, the evolution was positive with no aggravation of exophthalmia. At the moment the patient is still on a minimal dose of ATD with normal hormonal levels.

DISCUSSION

Our case illustrates the diagnostic difficulties in pediatric GD. The intensity of psychological disturbances overlapped the classical manifestation of thyrotoxicosis. The delay in diagnosis and treatment of GD in this 8 years old girl lead to interference in growth and development including increased height velocity rate. Moreover, due to behavioral problems, the compliance on medical treatment was very challenging. The improvement of the biological picture has been very difficult to achieve to. Long-term suppressed TSH along with fluctuations of fT4 and fT3 (which is more important as treatment efficacy marker in pediatric GD) were present throughout several months. The presence of anti-thyroid antibodies (TPOAb and TGAb) with stimulatory or inhibitory effect, in high titers can explain the irregular pattern of fT4 and fT3.

The literature indicates that remission rates in children are less than 25% following many years of ATD treatment. Puberty, TRAb levels and thyroid volume influence remission rates (1). Another particularity of this case was the weight of this girl that has been increased over the entire follow-up period. Commonly the children with GD present poor weight gain (4) due to hyper metabolism and hyperactivity. In our case the patient was overweight all the time despite the prolonged, uncontrolled thyrotoxicosis.

Pediatric Graves' disease is an autoimmune disorder due to thyroid stimulation by thyroid receptor antibodies (TRAb) (1). The pathophysiology of GD is not fully understood but it speculates the role of selenium (Se) in the lymphocytic chronic thyroiditis. Se supplementation has a stimulatory effect on glutathione peroxidases and thioreductases and inhibits the Human Leukocyte Antigen – DR isotype (HLA-DR) molecule (10, 11).

Beside the medical treatment with ATD in pediatric GD, the surgical option remains for cases which do not respond to ATD or develop serious adverse events (leucopenia, agranulocytosis). Total thyroidectomy is recommended in order to avoid the recurrence on the remaining thyroid tissue but the

post-operative complications such as hypoparathyroidism or recurrent laryngeal nerve injury should be considered (12, 13). The radioactive iodine use in pediatric GD represents an alternative to ATD and surgery (1).

Thyroid hormones have direct and important effect on brain function (8). Thyrotoxicosis in children is associated with neurological manifestations such as tremor, seen in the hands, face, and legs. Tremor is more commonly seen in pubertal/post pubertal than in prepubertal children (7) and is thought to be secondary to stimulation of the beta-adrenergic system and it is seen both at rest and with intention (7).

Other rare neurological manifestations in pediatric GD are: intermittent encephalopathy (14), acute confusional state (followed by thyroid storm) (15), choreiform movements (7). Seizures also can occur and vary from generalized tonic-clonic to complex partial, or more focal findings (7).

Hyperthyroid state can associate with cerebral ischemic events, and in most cases, patients recover from their neurologic symptoms after achieving euthyroidism. One possible explanation might be a hemodynamic compromise, induced by an increase in the cerebral metabolism and oxygen expenditure (16). Thyroid hormones may increase vascular sensitivity to the sympathetic nervous system and induce changes in the arterial walls. Vasculitis induced by antithyroid drugs may cause changes in the intracranial arteries. Cerebrovascular hemodynamic changes induced by thyrotoxicosis were considered to be responsible for the cerebral ischemic events. In addition, thyrotoxicosis-induced hypercoagulability may influence ischemic events (17, 18, 19). ADHD and autism spectrum disorder can mimic the onset of GD in children, so is very important always to test the thyroid function in children or adolescents with hyperactivity or comportment disorders (20, 21). Psychiatric disorders, loss of consciousness and movement disorders may all be manifestations of pediatric GD (8).

CONCLUSIONS

Neuro-psychiatric manifestations can be the first sign of thyrotoxicosis in children and adolescents. This may delay the diagnostic and proper treatment of thyrotoxicosis leading to important complications in pediatric GD. It is very important to assess the thyroid function in children with mild behavioral, mood disorders or neurological/ neuromuscular disturbances. A close collaboration with parents is required in order to have the desired results: euthyroidism and disappearance of neuro-psychiatric dysfunctions.

THE IMPACT OF SUBCLINICAL ATHEROSCLEROSIS TO THE PATIENTS WITH STROKE AND DIABETES (Abstract): **Aim** Atherosclerosis is a multifactorial disease, modulated by numerous risk factors and the basis for multiple micro and macro angiopathic pathologies. The main risk factor that triggers atherosclerosis and thickening of IMT is the increased cholesterol level. Smoking, obesity, arterial hypertension and increased glycemia are also risk factors for atherosclerosis. **Material and methods**: This paper aims to perform a retrospective study including patients presenting with a history of ischemic stroke diagnosed clinical and by native cerebral computer tomography, in which intima-media thickness (IMT) was evaluated at bilateral carotid level as an independent risk factor in relation to cholesterol, glucose and body mass index. **Results**: The statistical analysis showed a significant difference between high cholesterol and glycemia values, but also for IMT in common carotid artery and glycemic values. Although mean IMT was increased in stroke patients, statistical data analysis revealed that there was no significant difference between the IMT at the common and internal carotid arteries and the cholesterol levels. In our study, the patients with hypercholesterolemia had a normal IMT (80.9%). 19.1% of patients with stroke and hypercholesterolemia show a linear decrease of IMT with lowering cholesterol levels, similar to the trend observed at ACC level. **Conclusions**: The stroke patients who also had diabetes mellitus have an increased value of IMT, so it is once again confirmed that diabetes, along with stroke, represents an important risk factor in the process of atherosclerosis. **Keywords**: ATHEROSCLEROSIS, INTIMA MEDIA THICKNESS, CHOLESTEROL.

Atherosclerosis is a multifactorial disease, modulated by numerous risk factors and the basis for multiple micro and macro angiopathic pathologies. It is considered to be an infiltrative and degenerative process that associates both lipid deposits in the intima and a fibrous reaction (1, 2). The first lesions of atherosclerosis occur in the second decade of life, but this does not become symptomatic until after the sixth decade of age (3). It can be detected in a subclinical stage through intima-media thickness measurements at the carotid level (IMT), ankle-branch index, arterial calcification score and arterial stiffness (4, 5).

The main risk factor that triggers atherosclerosis and thickening of IMT is the increased cholesterol level. Smoking, obesity,

arterial hypertension and increased glycemia are also risk factors for atherosclerosis (6, 7). Diabetes mellitus is an independent risk factor for cardiovascular and cerebrovascular disease in both women and men. The risk of hyperglycemia is also present in people with obesity and metabolic syndrome (8, 9). Cardio and cerebrovascular diseases are the main cause of mortality and morbidity among people with diabetes, where their prevalence is up to 55% (10).

Stroke represents one of the most important cause of long-term disability of the middle and elderly age population. Approximately 4.4 million people die from the consequences of stroke each year, which accounts for about 9% of all deaths worldwide, 88% of these in people over 65 years old (11, 12). Risk factors for atherosclerotic stroke seem to be important: age, gender, hypertension, tobacco, obesity, hyperlipidemia, diabetes, alcohol consumption, oral contraception and family history (13). It appears that a major role lies in the hyperlipidemic risk factor further investigated in experimental and clinical studies. In some cases, an established stroke is preceded by a TIA (transient ischemic accident), when the neurological deficit occurs suddenly, in full health and is of short duration. The most common cause of TIA is carotid artery and vertebral artery atherosclerosis or thrombosis. The association of stroke with type 2 diabetes increases mortality by approximately 55% (14). Since both pathologies result from the interaction between genetic predisposition and vascular risk factors, identifying common elements could lead to the development of primary and secondary prevention recommendations.

Atherosclerosis is a process underpinning multiple vascular and non-vascular comorbidities and recent studies offer promising results on the role of IMT both as an independent risk factor for stroke and type 2 diabetes mellitus, but also as a prognostic factor. According to the current guidelines in all patients who have a history of stroke, it is recommended to use statins as a prognostic element, as on the one hand they lower the cholesterol value and on the other hand stabilize the already formed atherosclerotic plaque (15, 16, 17).

MATERIAL AND METHODS

This paper aims to perform a retrospective study including patients presenting with a history of ischemic stroke diagnosed clinical and by native cerebral computer tomography, in which IMT was evaluated at bilateral carotid level as an independent risk factor in relation to cholesterol, glucose and body mass index (BMI).

The main exclusion criteria involved any embolic conditions, atheroma plaques, stenosis or occlusion in the carotids or a value of the IMT more than 1.5 mm. In the present study, all subjects before being examined were informed of the research method and signed an informed consent. The batch was examined by the same person, with the Siemens Accuson X300 system using a 7.5 MHz linear probe via a standardized method, in mode B, on a longitudinal section, at the level of both common (CCA) and internal (ICA) carotid arteries, bilaterally (18). The IMT measurement was performed at the distal wall of the CCA and ICA, at 10 mm of the bifurcation, in the area without any atheroma plaque (19). The value used for the subsequent statistical analysis was the average of the three measurements on each side. Medium IMT values greater than 1 mm were considered elevated. No values greater than or equal to 1.5 mm were considered (these representing the formation of the atherosclerotic plaque). We also measured:

weight, height, total cholesterol and glycemia levels. Based on these anthropometric parameters, the body mass index (BMI) was calculated according to the formula: G (kg)/T^2 (m^2). BMI is the most used surrogate parameter to estimate excess weight. A level of cholesterol above 200 mg/dL was considered increased and for glycemia above 100 mg/dL.

Statistical analysis

In interpreting the statistical results, the reference value of significant values p = 0.005 was considered, which corresponds to a confidence interval of 95%. Continuous type variables were presented as mean ± standard deviation. The statistics was performed in *SPSS v.18.0*

RESULTS

We gathered 47 patients in our study distributed evenly, the total gender distribution included 22 females (46.80 %) and 25 males (53.20 %). The mean age was 52.7 years old and the average BMI was 26.5 kg/m^2.

In our study, there is a direct proportional relationship between cholesterol and IMT at common carotid artery (CCA) level in patients with previous stroke. The mean value of 300 mg/dL is the mean value at which the average intima thickness is maximal. Regardless of the increase in cholesterol, the average intima thickness is no longer altered. If cholesterol is between 200 and 300 mg/dL, IMT is maintained as high as in patients with cholesterol levels of 300 mg/dL or above. This is also confirmed in the statistical analysis, with no statistically significant difference (fig. 1). The usefulness of hypolipidemic medication results in the stabilization of the atheromatous plaque without influencing IMT.

The same tendency is observed between cholesterol values and mean intima media thickness at the left CCA. This time, there is a decrease in IMT with decreasing cholesterol. Thus, although there is no statistically significant difference between the studied parameters, a hypolipidemic medication is required to diminish the IMT and help stabilize any existing cholesterol plaques (fig. 2).

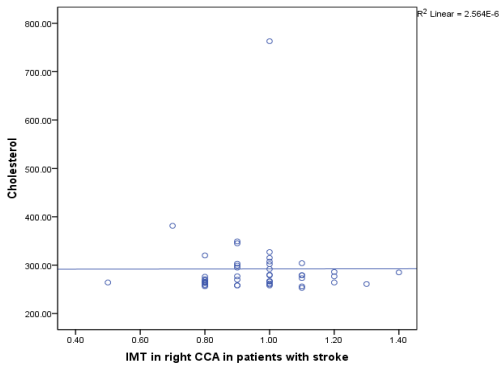

Fig. 1. Correlation of IMT at the right CCA with cholesterol

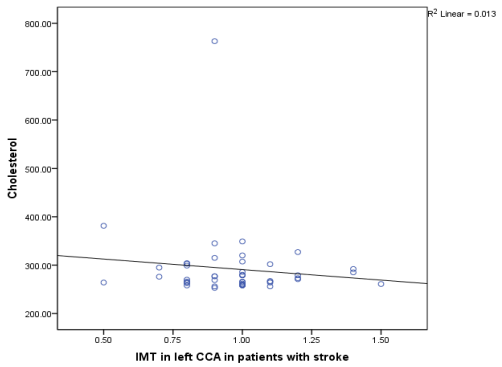

Fig. 2. Correlation of IMT at the left CCA with cholesterol

There is no statistically significant difference between the three groups of patients, but the decrease in cholesterol in patients with hypercholesterolemia is inversely proportional to increases in glycemic values. Thus, most patients with ele-

vated cholesterol levels have normal glycemia, and those with hypocholesterolemia have elevated glycemic levels. Also, the statistical analysis objected to a significant difference between high cholesterol and glycemia (p = 0.000) (fig. 3). This fact is inconsistent with the data from the literature to confirm once again the potency of these parameters in the development of the atherosclerotic process.

Another parameter monitored in the study is the body mass index (BMI). Most stroke patients had grade I obesity. Statistical data analysis revealed that there was no statistically significant difference between cholesterol and body weight (fig. 4).

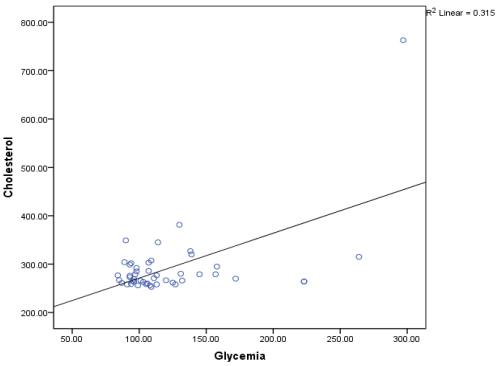

Fig. 3. Correlation of glycemia with cholesterol

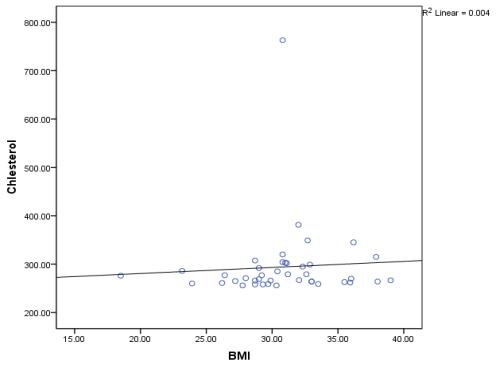

Fig. 4. Correlation of BMI with cholesterol

Increasing the mean interstitial thickness would be partly due to changes in the parietal level due to the slightly higher flux in the left carotid system than the right one in the right patients, and because of the changes associated with the preexisting comorbidities: diabetes, hypertension, obesity, hypercholesterolemia (fig. 5).

In our study we find that 14.89% of diabetic patients have an increased value of IMT, a statistically significant percentage (p = 0.047), so it is once again confirmed that diabetes represents an important risk factor in the process of atherosclerosis (fig. 6).

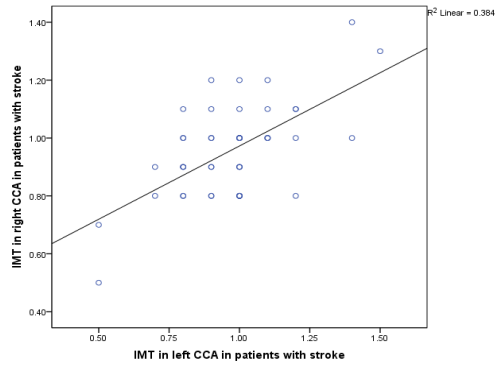

Fig. 5. Correlation of IMT at the left and right CCA

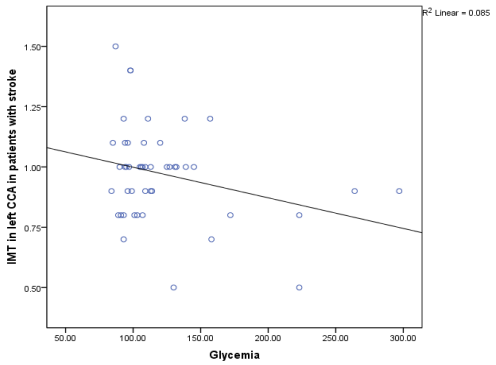

Fig. 6. Correlation of IMT at the left CCA and glycemia

DISCUSSION

In our study, the patients with hypercholesterolemia had a normal IMT (80.9%). The data obtained by us at the level of the right internal carotid artery (ICA) are in contradiction with the data obtained at the bilateral ACC and with the literature.19.1% of patients with stroke and hypercholesterolemia show a linear decrease of IMT with lowering cholesterol levels, similar to the trend observed at ACC level. So, we can once again say that hypolipidemic medication causes IMT to decrease but this decrease is not statistically significant. Liping *et al.* in a recent study had also a decrease of the IMT after 6 months of treatment with rosuvastatin or atorvastatin, but with a statistical significance compared to the values before treatment ($p<0.05$) (20).

The same trend is observed between cholesterol and IMT, respectively, at the level of the left ACI. Although insignificantly statistically from the previous group, only 25.5% of patients with hypercholesterolemia exhibit changes in IMT at the left ACI level. The decrease in IMT with decreasing cholesterol is less steep, maintaining almost constant although cholesterol values range between 253 and 763 mg/dL. And this time, the results are not in line with those in the literature and there is no statistically significant difference between cholesterol and IMT. Guideline recommendations on the usefulness of hypolipidemic medication are only reflected in the stabilization of the atheroma plate without affecting the value of the cholesterol (15).

The main risk factors in the atherosclerotic process are diabetes mellitus and hypercholesterolemia. We have tried to see if there is any relationship between the presence of hypercholesterolemia and the amount of glucose. The highest blood glucose level was observed in 29.79% of patients with hypercholesterolemia, a decrease in glucose tolerance was seen in 31.91% of patients and 38.3% had normal blood glucose.

It is known that overweight and obese patients often have elevated cholesterol levels. This can also be observed in our study. Thus, 41.5% of patients with hypercholesterolemia were obese grade I, 17.1% had grade II obesity, 34.1% were overweight and only 7.3% had a normal weight. So, there is no direct proportional relationship between cholesterol and weight.

In the studied group a statistically significant difference between IMT at right and left level ($p = 0.000$) was observed. This is consistent with literature data knowing that most of the right-handed patients have a slightly higher carotid IMT value physiologically.

There is also a direct proportional relationship between modified blood glucose and IMT. Thus, we note that 19.15% of patients with modified basal blood glucose have increased IMT and 12.77% have normal IMT value. In patients with stroke and diabetes, the highest thickness of IMT is observed. Thus, once again we can say that the main cause of stroke is carotid atheromatosis, to which vascular intraparietal changes are added due to the prolonged presence of diabetes. According to the current guidelines, patients with stroke and diabetes should be given hypoglycemic medication, but also hypolipidemic with the desire to stabilize the plaque and to reduce the average intima media thickness (15).

CONCLUSIONS

In our study, the mean IMT was increased in stroke patients, but statistical

data analysis revealed that there was no statistically significant difference between the IMT at the level of common and internal carotid arteries and the cholesterol levels. Patients with stroke and increased cholesterol levels showed a linear decrease of IMT with lowering cholesterol levels also at the ICA but with no significant difference. Also, no statistically significant difference was found between cholesterol and BMI. Most patients with elevated cholesterol levels have normal glycemia, and those with hypocholesterolemia have elevated glycemic levels.

NEWS

HYPERSENSITIVITY PNEUMONITIS. RADIOLOGIC PHENOTYPES ARE ASSOCIATED WITH DISTINCT SURVIVAL TIME AND PULMONARY FUNCTION TRAJECTORY

Hypersensitivity pneumonitis (HP) is an interstitial lung disease with a better prognosis, on average, than idiopathic pulmonary fibrosis (IPF). We compare survival time and pulmonary function trajectory in patients with HP and IPF by radiologic phenotype. HP (n = 117) was diagnosed if surgical/transbronchial lung biopsy, BAL, and exposure history results suggested this diagnosis. IPF (n = 152) was clinically and histopathological diagnosed. All participants had a baseline high-resolution CT (HRCT) scan and FVC % predicted. Three thoracic radiologists documented radiologic features. Survival time is from HRCT scan to death or lung transplant. Cox proportional hazards models identify variables associated with survival time. Linear mixed models compare post-HRCT scan FVC % predicted trajectories. Subjects were grouped by clinical diagnosis and three mutually exclusive radiologic phenotypes: honeycomb present, non-honeycomb fibrosis (traction bronchiectasis and reticulation) present, and nonfibrotic. Nonfibrotic HP had the longest event-free median survival (> 14.73 years) and improving FVC% predicted (1.92%; 95% CI, 0.49-3.35; p = .009). HP with non-honeycomb fibrosis had longer survival than IPF (> 7.95 *vs.* 5.20 years), and both groups experienced a significant decline in FVC % predicted. Subjects with HP and IPF with honeycombing had poor survival (2.76 and 2.81 years, respectively) and significant decline in FVC % predicted. Three prognostically distinct, radiologically defined phenotypes are identified among patients with HP. The importance of pursuing a specific diagnosis (e.g., HP *vs.* IPF) among patients with non-honeycomb fibrosis is highlighted. When radiologic honeycombing is present, invasive diagnostic testing directed at determining the diagnosis may be of limited value given a uniformly poor prognosis (Margaret L. Salisbury, Tian Gu, Susan Murray, Barry H. Gross *et al. CHEST* 2019; 155(4): 699-711).

REAL-LIFE PERCEPTION OF ACLF IN ROMANIA: RESULTS OF A SURVEY COMPLETED BY PRACTICIANS

REAL-LIFE PERCEPTION OF ACLF IN ROMANIA: RESULTS OF A SURVEY COMPLETED BY PRACTICIANS (Abstract): Acute-on-chronic liver failure (ACLF) is a relatively new concept introduced in order to better assess the risk of death in patients with acute decompensation of chronic liver disease. The diagnostic criteria are currently still under debate, but the most recent definition is based on the presence of acute decompensation of cirrhosis associated with organ failure according to the CLIF Consortium ACLF score (CLIF-C ACLF score). **Aim:** To establish the real-life perception of ACLF among Romanian practitioners. **Material and methods:** We assessed current diagnosis patterns for ACLF, and we developed a dichotomous question survey concerning the current knowledge on ACLF. The survey was sent by e-mail to the members of the Romanian Society of Gastroenterology and Hepatology (SRGH); a printed survey was completed by intensive care practitioners from "Sf. Spiridon" County Clinical Emergency Hospital Iasi, Romania. We evaluated the specialty of the practitioners included, the professional degree, and the participant's clinical and diagnostic abilities concerning the assessment of ACLF. **Results:** 263 practitioners responded to the survey: 69% gastroenterologists, 22% internal medicine consultants and 9% intensive care specialists; 31% of responders were trainees, 35% consultants and 34% senior consultants, most of them working in a university hospital (66%). The majority of the participants had heard of ACLF (94%). 73% of responders considered that there were unanimously accepted criteria for the diagnosis of ACLF. Almost all responders (98%) considered the liver to be the most common organ failure in ACLF patients. Most participants agreed that the younger and alcoholic patients had a higher risk for developing ACLF (84%) and that ascites degree was not relevant for the diagnosis (65%). **Conclusions:** The results show that knowledge of the diagnosis and characteristics of ACLF among practitioners in Romania are according with the current ACLF published criteria. However, the percent of practitioners that applied the ACLF criteria in clinical practice was not determined and could represent a subject for future research. **Keywords:** ACUTE-ON-CHRONIC LIVER FAILURE, LIVER CIRRHOSIS, ACUTE DECOMPENSATION, CLIF-C ACLF SCORE, SURVEY.

Liver cirrhosis (LC) is a chronic disease generally characterized by a long asymptomatic evolution. However, the diagnosis is frequently established in the setting of decompensation and/or complications such as variceal bleeding (VB), ascites, hepatic

encephalopathy (HE), acute kidney injury (AKI), and bacterial infections which associate a poor prognosis (1, 2). Moreover, the practitioners have been often surprised by rapid impairment of liver, kidney or circulatory function, in patients with known, yet stable liver cirrhosis. These observations suggested the existence of a distinct syndrome, different from the "mere" decompensation of liver cirrhosis, namely Acute-on-chronic liver failure (ACLF). Jalan R *et al*. were among the first to describe ACLF in 2002 (3), but since then many definitions have been proposed, most of them lacking solid clinical proof, which led to a discrepancy between the prevalence and clinical outcomes of ACLF reported by different authors (4, 5). Moreau *et al*. (6) conducted the first large prospective multicentric study, carried on in Europe (the CANONIC study) in which the authors defined ACLF as acute decompensation of liver cirrhosis associated with organ failure and high short-term mortality rates. The authors established specific criteria for the diagnosis of the syndrome. ACLF grade 1 was diagnosed in the setting of kidney failure or other single organ failure (OF) with a serum creatinine level between 1.5-1.9 mg/dL and/or Grade I-II HE. The diagnostic of ACLF grade 2 was set in the presence of 2 OFs and ACLF grade 3 in patients with 3 or more OFs. Moreau *et al*. defined liver failure as total bilirubin levels of more than 12 mg/dL, kidney failure as an increase of serum creatinine $\geq$ 2 mg/dL or the use of renal replacement therapy, cerebral failure as grade III or IV West Haven HE, coagulation failure as an INR value over 2.5 and/or platelet count $\leq$ 20 x 109/L, respiratory insufficiency as a partial pressure of arterial oxygen to $FiO_2 \leq 200$ or an SpO_2 to FiO_2 ratio $\leq$ 200, and circulatory failure in the setting of vasoactive drug therapy (6). The authors diagnosed ACLF in 30.9% of the participants included. Moreover, three grades of ACLF have been validated, each associating a different 28- and 90-day outcome (22.1% and 40.7% mortality rate for grade 1, 32% and 52.3% for grade 2, 76.7% and 79.1% for grade 3). In order to define organ failure and to assess disease severity several scores have been proposed, namely the Chronic Liver Failure Consortium Organ Failure (CLIF-C OF) score, a simplified version of the CLIF-C ACLF score (1, 7) (tab. I).

TABLE I

CLIF-C ACLF score

Organ System	Score=1	Score=2	Score=3
Liver (mg/dL)	Bilirubin<6	6 ≤ bilirubin ≤ 12	Bilirubin > 12
Kidney (mg/dL)	Creatinine <2	Creatinine ≥ 2 <3.5	Creatinine ≥ 3.5/ renal replacement
Brain (West Haven)	Grad 0	Grade 1-2	Grade 3-4
Coagulation	INR < 2.0	2.0 ≤ INR < 2.5	INR ≥ 2.5
Circulation	MAP ≥ 70 mm Hg	MAP < 70 mm Hg	Vasopressor therapy
Respiratory: PaO_2/FiO_2 or SpO_2/FiO_2	>300 >357	≤300 - > 200 >214 - ≤ 357	≤ 200 ≤ 214

Abbreviations: PaO_2, partial pressure of arterial oxygen; FiO_2, fraction of inspired oxygen; SpO_2, pulse oximetric saturation; MAP, mean arterial pressure; INR, international normalized ratio.

Certain precipitating factors of ACLF have been identified, such as active drinking and bacterial infection which were the most common but also gastrointestinal bleeding, therapeutic paracentesis without administration of intravenous albumin, placement of trans jugular intrahepatic portosystemic shunt, major surgery, viral hepatitis, and alcoholic hepatitis. Surprisingly, in 40.3% of the cases no precipitating event was identified, and the outcome was not influenced by the precipitating factor but rather by the number of organ failures. The most commonly identified failing organ in ACLF is the kidney; also, studies indicate that ACLF is associated with younger age and alcohol abuse and patients without any history of decompensation developed a more severe syndrome (6).

MATERIAL AND METHODS

The aim of our study was to assess the patterns of practice, disease awareness and recognition of ACLF among Romanian practitioners.

General information regarding the participants	
1. Please choose your specialitv	☐ gastroenterology ☐ intensive care ☐ internal medicine
2. Please choose your professional degree	☐ intern ☐ specialist ☐ consultant
3. Are you currently working in a university hospital?	☐ yes ☐ no
Knowledge of ACLF	
1. Have you heard of ACLF?	☐ yes ☐ no
2. In your opininon do you consider ACLF to be different from the acute decompensation of liver cirrhosis?	☐ yes* ☐ no
Diagnostic criteria for ACLF	
1. Do you consider that currently there are unanimously accepted criteria for the diagnostic of ACLF?	☐ yes ☐ no*
2. When you suspect the presence of ACLF, do you find the CLIF-OF score useful in establishing the diagnosis?	☐ yes* ☐ no
3. Is liver failure mandatory for the diagnosis of ACLF?	☐ yes ☐ no*
4. Is the degree of ascites relevant for the diagnosis of ACLF?	☐ yes ☐ no*
Particularities of ACLF	
1. Is liver failure the most commonly found organ dysfunction in ACLF patients?	☐ yes ☐ no*
2. Do younger or alcoholic patients pose a higher risk of developing ACLF than the others?	☐ yes* ☐ no
3. Is ACLF evolution more severe in patients with previous acute decompensation?	☐ yes ☐ no*
4. Is mortality in patients with ACLF similar or higher with those associating acute decompensation of liver cirrhosis?	☐ yes* ☐ no

*correct answer, ACLF=acute-on-chronic liver failure

Fig. 1. The survey used for the evaluation of the practitioners

We composed a survey based on the results of the CANONIC study (6) and consisting of questions regarding the current knowledge on ACLF (fig. 1). Most questions were dichotomous, and the questionnaire was designed to be as short and as little time consuming as possible.

The survey was sent by e-mail to the contact list of members of the Romanian Society of Gastroenterology and Hepatology (SRGH); additional printed survey were sent to intensive care practitioners from "Sf. Spiridon" County Clinical Emergency Hospital Iași, Romania. The questionnaire was divided into several sections; the first section included questions regarding to participant information (age, sex, place of practice, the professional degree, the affiliation to a university hospital). We emphasized gathering information regarding the participant's clinical and diagnostic abilities concerning the assessment of ACLF; thus, we distributed the questions according to the following criteria: knowledge of ACLF, diagnostic criteria of ACLF, and particularities in patients with ACLF. The survey was sent to the participants in March 2017. The responses were received from April to September 2017. The results of survey were expressed as percentage.

We were also interested in comparing our results with unpublished data presented by Trifan, *et al*. on 4th UpDate on Hepatology Course, April 6th-7th 2017, Bucharest, Romania (fig. 2). We were also interested in observing if the presentations held on ACLF during the meeting had an effect on the general concepts of Romania practitioners.

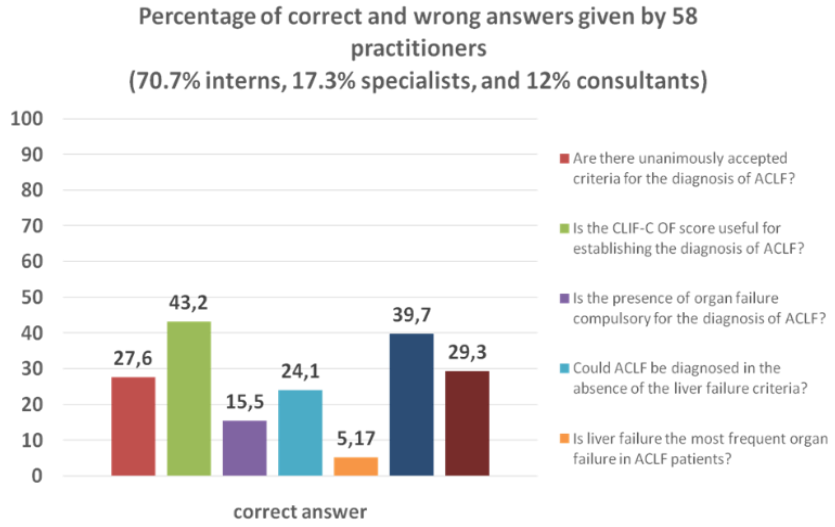

Fig. 2. Real-life perception of ACLF in Romania: results of a survey completed by practicians in a northeastern Romanian university tertiary care center

RESULTS

Out of 317 gastroenterology practitioners, members of SRGH, 181 (57%) responded. All of the 24 intensive care specialists that received the printed version of the survey responded. Out of 72 internal medicine consultants 58 (80%) responded. The total number of respondents was 263, and included 181

(69%) gastroenterologists, 58 (22%) internal medicine specialists and 24 (9%) intensive care specialists. Regarding the professional degree, 82 (31%) of responders were trainees, 92 (35%) were consultants and 89 (34%) were senior consultants.

Most practitioners said that they worked in a university hospital (66%).

The majority of the respondents said that they had heard of ACLF (94%) and seventy eight percent of them considered ACLF to be different from the "simple" acute decompensation of liver cirrhosis. 191 (73%) of responders considered that there were unanimously accepted criteria for the diagnosis of ACLF.

TABLE II
Results of the survey conducted

Question	Yes (%)	No (%)
1. Have you heard of ACLF?	94	6
2. Do you consider ACLF to be different from the acute decompensation of liver cirrhosis?	78	22
3. Do you consider that currently there are unanimously accepted criteria for the diagnosis of ACLF?	73	27
4. When you suspect the presence of ACLF, do you find the CLIF-OF score useful in establishing the diagnosis?	70	30
5. Is liver failure mandatory for the diagnosis of ACLF?	59	41
6. Is the degree of ascites relevant for the diagnosis of ACLF?	35	65
7. Is liver failure the most commonly found organ dysfunction in ACLF patients?	98	2
8. Do younger or alcoholic patients pose a higher risk of developing ACLF that the others?	84	16
9. Is ACLF evolution more severe in patients with previous acute decompensation?	94	16
10. Is mortality in patients with ACLF similar or higher with those associating acute decompensation of liver cirrhosis?	76	24

183 (70%) of responders considered the CLIF-OF score is useful in establishing the diagnosis of ACLF. When asked what organ dysfunction was the most common among patients with ACLF, almost all of them (98%) found liver failure to be the most commonly organ insufficiency. However, 41% of them stated that severe liver failure was not mandatory for the diagnosis of this syndrome. The degree of ascites was not considered relevant for the diagnosis of ACLF by more than half of the practitioners (65%) and a great proportion agreed that the younger and alcoholic patients had a higher risk for developing ACLF (84%). Data obtained from the survey is illustrated in table II.

DISCUSSION

ACLF was firstly mentioned by Sarin(8) and for a long time an evidence-based definition of ACLF was not established. The syndrome was characterized based on expert opinions and not on objective data. In 2014 more than13 definitions of ACLF were accepted (9).

According to WGO Consensus Definition ACLF is a syndrome distinct from acute liver failure(ALF) or decompensated cirrhosis in patients with chronic liver disease (with or without known cirrhosis), characterized by acute hepatic decompen-

sation (liver failure and one or more organ failures), associated with high mortality within 28 days and up to 3 months from onset (10).

ACLF is a newly defined concept, but our survey confirms that the majority of the Romanian practitioners have heard about this entity (94%) without significance depending on the specialty. Unfortunately, although having heard of ACLF most of practitioners do not know whether there are unanimously accepted criteria for the diagnosis of ACLF. Trifan A *et al*., on The 4th UpDate on Hepatology Course, 6th-7th April 2017, Bucharest, Romania reported that 27.6% of practitioners in a North-eastern Romanian university tertiary center were aware of unanimously accepted criteria for the diagnosis of ACLF. Our survey revealed that 73% of responders were confident with the diagnosis criteria. Diagnosis criteria for ACLF represent a subject still under debate and the answers of our responders show relative uncertainty, in accordance with the lack of unanimously accepted diagnostic criteria.

ACLF is defined as acute decompensation of liver cirrhosis associated with organ failure and high short-term mortality rates (6). The diagnosis is made in the setting of organ failure(s), as defined by the CLIF-C OF, a score developed by Moreau *et al*. by adapting the Sequential organ failure assessment (SOFA) score (used by all intensive care practitioners) in accordance with the particularities of cirrhotic patients. The SOFA score includes the evaluation of six types of organ failure: liver, renal, coagulation, cerebral, respiratory, and circulatory. One hundred and eighty-three of the responders (70%) considered the CLIF-C ACLF score useful in establishing the diagnosis of ACLF. The percent of correct responses is significantly higher compared to the percent reported by Trifan *et al*. in April 2017 during the 4th Update on Hepatology Course Bucharest, Romania. Unfortunately, we have no data of current evaluation of CLIF-C OF score (except for intensive care units) in daily clinical practice.

ACLF should be assessed in all patients with acute decompensation of cirrhosis: ascites grade 2 to 3 (according definition of International Ascites Club) within less than 2 weeks (first/new episode), acute hepatic encephalopathy in patients with previous normal consciousness (first/new episode), acute upper and/or lower gastrointestinal hemorrhage of any etiology and bacterial infections (any type of acute bacterial infection) in patients with liver cirrhosis. ACLF should not be assessed in patients with refractory ascites or chronic hepatic encephalopathy.

Although many of us do not use this score we emphasize that it is not very time consuming (easy access http://www.efclif.com/ scientific-activity/score-calculators/clif-c-aclf) and not more time consuming than calculating the CHILD or MELD scores, requiring no special equipment and therefore could find its place in clinical practice.

CONCLUSIONS

The prevalence of ACLF in Romania is currently unknown, but the mortality rate of patients with liver cirrhosis is known to be high, as liver cirrhosis has been considered the fourth cause for death in a recent WHO report with a mortality rate of 47.8/100,000 (11). ACLF is a newly introduced syndrome that benefits from increased attention; thus, we conducted a survey in a representative population of Romanian practitioners in order to assess

the current knowledge regarding this syndrome and to set the grounds for future prospective studies in our country. As Moreau *et al*. were the first to conduct a large prospective trial and the definition of ACLF was based on clinically relevant facts we chose to consider the criteria proposed by the authors in our survey. The results show that knowledge of the diagnosis and characteristics of ACLF among practitioners in Romania are according with the current ACLF published criteria. However, future research is needed in order to evaluate the percent of practitioners that apply the ACLF criteria in clinical practice.

EFECTUL TERAPIEI CPAP ASUPRA CALITĂŢII SOMNULUI LA PACIENŢII CU SAOS EVALUATĂ PRIN SLEEP DISTURBANCES INDEX (SDI)

Verona Mihai[1], Gianina Rusu[1], Tr. Mihăescu[1,2]
1. Spitalul Clinic de Pneumologie Iaşi
Universitatea de Medicină şi Farmacie "Gr.T. Popa" Iaşi
Facultatea de Medicină
2. Disciplina de Pneumoftiziologie

EFFECT OF CPAP THERAPY ON SLEEP QUALITY IN PATIENTS WITH OBSTRUCTIVE SLEEP APNEA SYNDROME (Abstract): For an adequate analysis of sleep quality was assessed a new composed index wich objectively approached variate polisomnographic parameters. We used this new concept – sleep disturbances index-SDI in patients with obstructive sleep apnea(OSAS), before and after the beginning of CPAP therapy. **Material and method**: 41 patients were evaluated and for each one we calculated SDI score. All patients were split in two groups according with apnea-hipopnea index (AHI), and we correlated SDI with AHI as marker of severity of the disease and with Epworth Sleepiness Scale's scores, as an subjective evaluation. After 1 month of CPAP therapy, SDI was reevaluated. **Results**: SDI is correlating with the severity of the disease: for group 1, with $5 < AHI < 15$, SDI= 2.24 ± 0.88, $r = 0.53$, $p < 0.01$ and for group 2, with $AHI > 15$, SDI= 3.23 ± 0.69, $p < 0.01$, $r = 0.46$. There was no significant correlation between SDI and ESS scores ($r = 0.23$, $p < 0.01$). SDI lowers significant during CPAP therapy: SDI= 1.48 ± 0.60, respectiv SDI= 1.90 ± 1.23. **Conclusion**: The severity of OSAS is correlated with increased SDI, but can be seen interindividual variability. The effect of CPAP therapy is reflecting also in sleep quality. **Key words**: SDI, OSAS, SLEEP QUALITY

AGREEMENT RATE AMONG ONCOLOGISTS FOR SYSTEMIC THERAPIES IN THE REGIONAL INSTITUTE OF ONCOLOGY IASI

AGREEMENT RATE AMONG ONCOLOGISTS FOR SYSTEMIC THERAPIES IN THE REGIONAL INSTITUTE OF ONCOLOGY IASI (Abstract): In recent years, cancer treatment has become more complex due to the increasing involvement of other specialists in the multimodal approach and to the constant innovations and changes brought on by the discovery and approval of new drugs. As such, the multidisciplinary team (MDT) management model has been implemented in most European countries, including Romania. Material and method: We performed a retrospective analysis of all cases eligible for systemic therapy that were discussed in the MDT of the Regional Institute of Oncology Iasi between January 2017 and December 2018. For each case, we recorded several parameters, together with data regarding the agreement rate between the proposed treatment and the final MDT decision. Results: We identified 723 cases that respected the inclusion criteria. Patients most often discussed in the MDT had been diagnosed with colorectal (29%), breast (22.7%) and lung cancer (18.7%). The most common reason why the cases were discussed was the initiation of biological therapies and immunotherapy. Agreement rate between the proposed treatment and the final MDT decision was 92.1%, with changes being suggested by the MDT most often in the case of breast (26.3%), colorectal (22.8%), prostate (17.5%), and lung cancer (7%). Conclusions: MDTs have become an essential part of cancer care. Although in Romania, they do not yet have legal responsibility, they offer an opportunity for medical professionals to interact and together decide the best outcome for patients diagnosed with solid tumors. **Keywords**: CANCER, MULTIDISCIPLINARY TEAM, SYSTEMIC ANTICANCER TREATMENT.

The multidisciplinary team (MDT) has brought many benefits to patients in all medical fields, especially in oncology, where its importance derives from the complexity of cancer disease (1) and from the need for collaboration between clinical and paraclinical specialties, highlighting the importance of the holistic approach in cancer treatment. Although MDT benefits are almost self-evident, demonstrating the efficacy of this type of collaboration is abstract and the barriers against it are more difficult to perceive. Participating in regular meetings of the MDT requires significant time and financial costs, as well as effective coordination (2-5).

The legal frame by which MDTs operate in Romania was set by Order 1202 of

2017 on the establishment, organization and functioning of the specialized committees and subcommittees of the Ministry of Health. The oncological committees are an advisory board with mediation responsibilities and do not assume legal responsibilities regarding the patient rights and malpractice issues (6). Consequently, the attending physician is the one that has the medico-legal responsibility and the MDT's decision is not definitive. Within the Regional Institute of Oncology (IRO) Iasi, a multidisciplinary team has been implemented in order to help physicians establish the diagnosis, to identify optimal therapeutic solutions, to integrate palliative medicine and end-patient care, improving interdisciplinary communication and stimulating clinical research.

The purpose of this retrospective study was to identify the efficacy of MDT for systemic treatment decisions in IRO Iasi, the utility of this approach in clinical routine and the agreement rate among oncologists.

MATERIAL AND METHOD

In the Regional Institute of Oncology, Iasi, the multidisciplinary team meetings are held weekly with the participation of medical oncologists, pathologists, surgeons, radiotherapists and radiologists. The result of the discussions is recorded by the secretary of the commission and signed by all members. It should also be noted that there is a custom that the discussions go on until everybody agrees and a unanimous decision is reached. When the members disagree on a topic, the case is discussed again after more patient data is available.

We performed a retrospective study of all cases presented in the MDT that were not eligible for local curative therapies (such as surgery or radiotherapy) and were referred by their oncologist for systemic therapy. To investigate the efficacy of these committee meetings and the agreement rate, we have considered data like diagnosis, cancer stage, committee decision and type of treatment. Consecutive patients who were presented to the committee between January 2017 and December 2018 that respected the selection criteria were included. Data were analyzed using *SPSS* software (IBM *SPSS Statistics for Windows, Version 21.0*. Armonk, NY: IBM Corp.).

RESULTS

From 5946 new cases presented in our institution for treatment decision or second opinion we identified 723 consecutive cases presented to the MDT in the specified time frame. Clinical and pathological characteristics of patients are summarized in first table.

Most frequently discussed by the committee were patients diagnosed with colorectal (29%), breast (22.7%) and lung cancer (18.7%) (tab. II). In women, the most common cancers were breast and colorectal, while for men it was colorectal, followed by lung cancer. The most common reason why the cases were discussed was the initiation of biological therapies and immunotherapy such as bevacizumab (22.5%), trastuzumab (13.3%) and nivolumab (9.5%) (tab. III).

Most frequently discussed by the committee were patients diagnosed with colorectal (29%), breast (22.7%) and lung cancer (18.7%) (tab. II). In women, the most common cancers were breast and colorectal, while for men it was colorectal, followed by lung cancer. The most common reason why the cases were discussed was the initiation of biological therapies and

immunotherapy such as bevacizumab (22.5%), trastuzumab (13.3%) and nivolumab (9.5%) (tab. III).

Most patients were recommended combined systemic treatment: chemotherapy and biological treatment (40.5%), only biological treatment (28.2%), or only chemotherapy (9.7%). Radiotherapy was recommended in 8 cases (1.1%) and surgery in 4 cases (0.6%), in contradiction with the treatment initially proposed. Of the patients presented, 30.6% were referred by the same oncologist; 79% of the cases were discussed only once in the committee, 20.3% twice and 0.7% three times during the course of their disease.

TABLE III

Therapies indicated following the discussion of the case in committee

Drug	Patients, n (%)	Drug	Patients, n (%)
Bevacizumab	163 (22.5%)	Olaparib	6 (0.8%)
Trastuzumab	96 (13.3%)	Gefitinib	6 (0.8%)
Nivolumab	69 (9.5%)	Erlotinib	6 (0.8%)
Chemotherapy	66 (9.1%)	Dabrafenib/Trametinib	6 (0.8%)
Cetuximab	43 (5.9%)	Crizotinib	5 (0.7%)
Pemetrexed	39 (5.4%)	Aflibercept	4 (0.6%)
Sorafenib	28 (3.9%)	Pazopanib	4 (0.6%)
Imatinib	25 (3.5%)	Axitinib	4 (0.6%)
Palbociclib	24 (3.3%)	Trabectedin	3 (0.4%)
Trastuzumab emtansine	23 (3.2%)	Lapatinib	3 (0.4%)
Abiraterone	17 (2.4%)	Palliative care	2 (0.3%)
Sunitinib	16 (2.2%)	Tamoxifen	2 (0.3%)
Afatinib	11 (1.5%)	Osimertinib	1 (0.1%)
Enzalutamide	11 (1.5%)	Olaratumab	1 (0.1%)
Panitumumab	9 (1.2%)	Pertuzumab	1 (0.1%)
Local treatment	7 (1%)	Aromatase inhibitor	1 (0.1%)
GnRH analogue	7 (1%)	Methotrexate	1 (0.1%)
Ramucirumab	6 (0.8%)	Vemurafenib	1 (0.1%)
Octreotide	6 (0.8%)		

Following the discussion, the treatment proposed by the committee agreed with the choice of the attending physician in 92.1% of the cases. The treatment was changed in 7.9% of cases (57 patients), either the physician chose another treatment, or the committee changed the decision of the attending physician. In this group, the patients were followed up instead of the active treatment in 52.6% of the cases, received hormonal therapy (instead of chemotherapy or biologics) in 36.8% of cases and symptomatic treatment in 5.2%. These discrepancies were found in cases of breast (26.3%), colorectal (22.8%), prostate (17.5%), and lung cancer (7%).

DISCUSSION

The purpose of this study was to quantify the effect of discussing patients with different neoplasms within a multidisciplinary committee and to analyze the rate of agreement between the decision of the committee and the attending physician. This is especially relevant for Romania, because, although this country has reimbursed most modern oncological drugs, it is a country with small to medium resources, and the regulatory bodies limit the prescription of these drugs by strict criteria protocols. As such, the MDT's decision is mostly consultative, as it is not entitled to modify or override the provisions of these protocols. Furthermore, the attending physician might still choose to reside on his/her own skills and experience, instead of the MDT's opinion, when selecting the treatment.

A retrospective review by Greer (7) and his collaborators including patients with gynecological neoplasms showed that their management was changed in 20% of cases after being discussed in an MDT. Another study, which included 75 breast cancer patients, concluded that MDT members did not agree with the attending physician's

decision in 43% of cases (8). According to a cohort study, the introduction of multidisciplinary teams in the management of breast cancer led to a decrease in mortality by 18% (9).

In our analysis, 29% of the patients subject to discussion were diagnosed with colorectal cancer. Available data from similar research sets show an improvement in 5-year survival for colorectal cancer patients presented in a multidisciplinary committee: 52.3% *vs.* 33.6% ($p < 0.00001$). However, for patients with incipient disease, the committee did not have a significant effect on survival. This suggests that the committee's main contribution may be to coordinate management of patients with a complex pathology such as potentially resectable liver metastases or borderline resectable tumors (10).

The results of a study involving patients with rectal cancer showed that the existence of a multidisciplinary committee and the possibility of discussing the cases led to the modification of the treatment plan in 29% of cases, with 42% of the changes being attributed to the reinterpretation of the imaging assessments (11), which is especially relevant since there are several new types of imaging techniques being investigated in digestive cancers (12). However, the work of Ryan and colleagues (13) showed that not all patients with colorectal neoplasm benefit from the input of a multidisciplinary committee, with only 3.4% of early colorectal cancer patients having their management plan changed. In contrast, management changed in 50% of complex cases: patients with associated pathology, preoperative rectal neoplasm management, and disease recurrence or resection criteria. The author of the study proposes a two-tier approach of the committee: all patients should be presented during the committee meeting but only cases with a complex pathology and non-standard therapeutic indications should be discussed in detail. This approach to the committee is also the one used in our institution.

In the present study, lung cancer was the third most common neoplasia (18.7%). Modern bronchopulmonary neoplasm management should be multidisciplinary, given the multiple treatment options and the potential long-term side-effects such as neuropathic pain (14). A study in France evaluating the efficacy of a committee in the management of lung cancer showed that the discrepancy between planned and actual treatment was 4.4% (15). This group of patients had lower survival but the difference between the two groups was not statistically significant. Forrest and his collaborators (16) have studied the management of patients with inoperable lung cancer before and after the cases were discussed in a committee; they have seen an increase in the use of chemotherapy in the group of patients discussed in committee (23% *vs.* 7%) but also an increase in median survival (6.6 months *vs.* 3.2 months). Similar data was reported by another study (17). In the case of elderly lung cancer patients discussed in a committee, an increase in the rate of curative or palliative radiotherapy and an improvement in 1-year survival rate (23.5% *vs.* 18.3%) have been observed. However, the data is controversial. Boxer *et al*. showed in his study that presenting lung cancer cases in a multidisciplinary tumor board was associated with a higher probability of radiotherapy and chemotherapy administration, with a potential impact on the quality of life of patients but without influencing their survival (18). Another study in Australia, which included 98 patients with inoperable lung cancer, concluded that there was no difference in

treatment for patients who were or were not discussed in a multidisciplinary committee but there was a difference in survival (237 *vs.* 208 days) in favor of the patients discussed in the committee. It is worth mentioning that the study focused on the evaluation of treatment and survival, but there are other goals such as waiting time, satisfaction or quality of life, which can be equally important (19).

A retrospective analysis showed that changes in treatment recommendations occurred in more than one-third of patients with gastrointestinal malignancies after a multidisciplinary team meeting. Change in management was recommended in 36%; 72% were major and 28% were minor. Agreement rate between the committee's decision and the treatment followed by the patient was 77% (20).

Regarding lung cancer, multidisciplinary team had an 80% agreement on risk factors, biopsy, staging, treatment and follow up of patients (21). Another survey among the multidisciplinary lung cancer team showed a 95% agreement rate regarding staging, 99% regarding treatment plan and 74% regarding the follow up (22).

The introduction of the multidisciplinary team in the present study led to a 92.1% agreement rate among oncologists for systemic therapies. These data support multidisciplinary communication and approach within a team dedicated to the management of oncological patients, which is extremely necessary given the complexity of pathology, the profile of side effects and their comorbidities. Optimal collaboration between oncologist, radiotherapist, surgeon, pathologist, and radiologist should improve the results of multimodal treatment. Additionally, patient preference and adequate informed consent should also be an important factor when deciding on optimal management and/or including the patient in a clinical study.

The present study has some limitations which may affect data interpretation. First, although it included a large number of cases, it is still a retrospective analysis and case selection bias must be considered. Second, it is likely that not all patient data was recorded in a unitary fashion, which is why some information might be missing. However, despite these limitations, the results clearly indicate that the MDT can change treatment course in some patients and its implementation is beneficial.

CONCLUSIONS

The organization of the multidisciplinary committee is mandatory in all oncology institutions. In addition to the benefits for patients, this way of managing cases leads to an interdisciplinary communication which will also improve the activity within the institution, from both the professional and the social/collaborative perspectives. In the end, we have to underline the pressure imposed by the insurance company on all oncologists to which the MDT might be a solution to share the financial responsibility.

REDUCTION OF SPLENIC VOLUME AFTER DIRECT ACTING ANTIVIRALS TREATMENT IN PATIENTS WITH HCV COMPENSATED CIRRHOSIS (Abstract): The **aim** of this study was to evaluate the impact of direct-acting antivirals (DAAs) treatment on spleen size and portal circulation after the achievement of sustained virological response (SVR) in patients with hepatitis C virus (HCV)-related cirrhosis. **Material and methods:** CT examination was performed in 60 patients with HCV-related compensated cirrhosis before and within 6-18 months after the treatment with Ombitasvir/ Paritaprevir/ ritonavir + Dasabuvir. The CT changes of spleen were assessed by measuring spleen volume. Portal trunk, splenic and superior mesenteric vein diameters have been assessed as part of portal hypertension. **Results:** Splenic volume was considerably higher before treatment (median: 564.79 mm^3, IQR: 342.54) than after (median: 474.45 mm^3, IQR: 330.00), z=-2.500, p=0.012. The portal vessels diameters showed no significant changes. **Conclusions:** There is a statistically significant reduction in size of spleen in patients with HCV-related compensated cirrhosis who achieved SVR after treatment with DAAs and this can be used as a sensitive imaging marker to assess improvement in cirrhotic patient's condition. **Keywords:** SPLENIC VOLUME, CIRRHOSIS, HEPATITIS C VIRUS, COMPUTED TOMOGRAPHY, DIRECT-ACTING ANTIVIRALS.

Spleen is the largest lymphoid organ in the body with elaborate tissue and vascular architecture. It plays an important role in the modulation of the immune system and filtration of blood from antigenic particles and from aged or abnormal cells. There is more than one reason to consider that spleen and liver are strongly connected. Both organs are important anatomic components of portal circulation. From histological perspective, spleen and liver have a similar reticuloendothelial structure and participate to cellular migration and substance exchange. Last, but not least, both have an essential role in immune hemostasis and pathogen clearance (1). Due to

these tight and variate connections, the concept of "liver-spleen axis" has been used in various conditions (2, 3).

This interconnection is responsible on the one hand for the morphological changes of the spleen in different liver pathologies, as well as for the influence exerted by the abnormal spleen on the liver and the portal venous system. This both-ways influence is also visible in HCV-related cirrhosis where splenomegaly is one of the most common abnormalities that accompany liver cirrhosis.

Splenomegaly is associated with poor prognostic in liver cirrhosis and is used as an index on sectional imaging techniques such as ultrasound, computed tomography, and magnetic resonance for non-invasive assessment of esophageal varices and risk of hemorrhage (4).

Hypersplenism, present in parallel with the increase in the volume of the spleen, is considered the main cause of blood dyscrasia such as cytopenia and thrombopenia in cirrhotic patients.

Patients with cirrhosis and splenomegaly have splenic blood flow increased, and portal congestion is considered the initial cause of splenic enlargement during liver cirrhosis (5). In the end splenic tissue hyperplasia stands as the main cause of increased spleen size instead of portal congestion (6). Moreover, the spleen actively congests the portal system participating in the maintenance of portal hypertension (7).

Spleen also influences the hepatic immune microenvironment both by cell migration and the secretion of splenic soluble factors via portal blood flow (1). Splenic red pulp macrophages are a major source of transforming growth factor β1 and are significantly correlated with the progression of liver fibrosis via liver-spleen cross-talk (8).

Spleen modulates also liver regeneration, aspect highlighted by studies who have demonstrated that splenectomy improved liver regeneration in cirrhotic patients (9).

Advances in understanding the of HCV molecular biology have led to the development of direct-acting antivirals (DAAs) for treatment. Currently chronic hepatitis C is the only chronic viral infection that can be cured with antiviral therapy (10,11).

The elimination of the causative agent and the interruption of the perpetuation of the inflammatory process after the antiviral treatment can also have an effect on the portal circulation with the improvement of the blood flow (12). The spleen as an integral part of the portal venous system may react to changes at this level secondary to improved liver condition. The purpose of this study was to evaluate the impact of DAAs treatment on spleen size and portal circulation after the achievement of sustained virological response (SVR) in HCV related cirrhotic patients.

MATERIAL AND METHODS

Study design. This is a prospective study on patients with genotype 1 HCV-related compensated cirrhosis who have reached SVR after treatment with DAAs (Ombitasvir/Paritaprevir/ritonavir + Dasabuvirum. Information from 60 cases with virus C related cirrhosis who underwent treatment with DAAs was collected within a 5-year period from January 2015 to December 2019.

Each patient had a CT scan before treatment to rule out liver malignancy and to assess both morphological and dimensional changes in the liver. In addition, the scan evaluates the manifestations of portal

hypertension such as dilation of the portal system, portosystemic collateral circulation, and splenomegaly. A second CT examination was performed after the treatment, within 6 and 18 months following SVR achievement.

The local Ethical Committee approved this study. Written informed consent was obtained from each patient and the study was conducted according to the Declaration of Helsinki.

Scanning protocols. We used a Siemens Sensation® 16 slice configuration CT scanner (Siemens AG Medical Solution) available in our institution. Our scanning protocol includes non-enhanced scan followed by i.v. administration of iodine-based contrast medium with tri-phase liver scan (arterial, portal and equilibrium phase) in order to exclude liver malignancy.

To evaluate the dilation of the portal system, a consequence of portal hypertension, the average diameters (reported in millimeters) of other portal trunk, splenic veins and superior mesenteric vein were measured.

The splenomegaly was quantified using the index value (product of cranio-caudal dimension, maximum size in axial plane and maximum thickness in axial plane) and the splenic volume (index value x 0.58 + 30) in milliliters (13). Since both, the splenic index, and the splenic volume, are interrelated, we selected for evaluation only the splenic volume.

RESULTS

Statistical evaluation began with the inspection of continuous variables to assess the normality of distributions. Since most of the differences did not meet the normality requirement, comparisons between the two sets of measurements, to see whether there were any changes in parameter levels, were performed with the Wilcoxon signed-rank test. A value of $p < 0.05$ was considered statistically significant. All results are summarized in first table and the boxplots of variables is shown in figure 1.

The volumes of the spleen before the treatment (*median: 564.79 mm^3, IQR: 342.54*) were significantly higher than the volumes determined after the treatment (*median: 474.45 mm^3, IQR: 330.00*), *z=-2.500, p=0.012*. An example of a reduction in the volume of the spleen after antiviral treatment is shown in figure 2.

In our study there were no significant differences before and after treatment between the average diameters of the main vessels of the portal system. This aspect was found in both the portal trunk (*p = 0.831*), the splenic vein (*p = 0.536*) and the superior mesenteric vein (*p = 0.624*).

TABLE I

Pre and post treatment comparation of splenic volume and portal vessels diameters

	Before treatment		After treatment		Z (Wilcoxon)	p
	median	IQR	median	IQR		
Splenic volume (mm^3)	*564.8*	*342.54*	*474.5*	*330.00*	*-2.500*	*0.012**
Portal trunk diameter (mm)	13.73	2.70	13.78	2.00	-0.214	0.831
Superior mesentery vein diameter (mm)	12.7	2.90	12.2	2.70	-0.491	0.624
Splenic vein diameter (mm)	9.85	3.30	10.2	3.73	-0.618	0.536

IQR - interquartile range

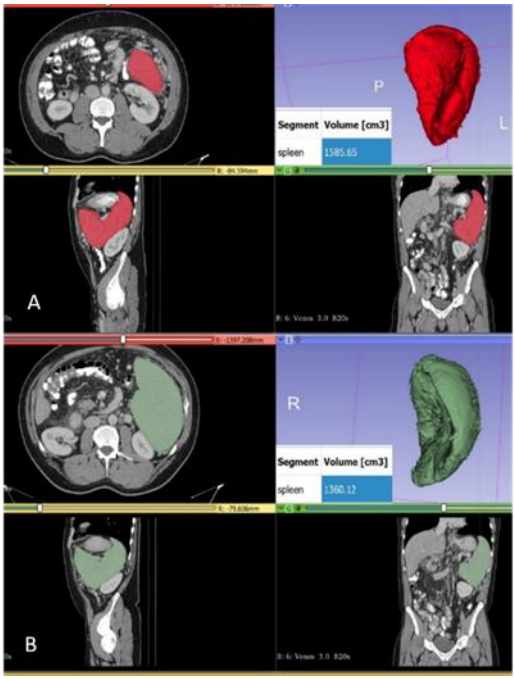

Fig. 2. Splenic volume before (A) and after treatment (B)
showing important reduction of spleen volume after DAAs treatment.
Note: the 3D segmentation of spleen was performed using *3D Slicer software v. 4.11.0*.

DISCUSSION

In the evaluation of the portal system vessel diameter variations we observe no statistically significant changes. This absence of modifications may reflect a balance between two opposite influences: one tendency is to reduce diameter of vessel to compensate blood flow reduction and the second tendency is to enlarge due to portal hypertension. The same situation was observed in other studies that assessed the vasculature of the cirrhotic patients (14, 15).

The improvement of the portal circulation is indicated by the decrease of the splenic volume. This reduction in volume may be the combined result of decreased portal hypertension and general inflammatory status.

This leads to the conclusion that this reduction in splenic volume could be a sensitive marker for the overall improvement of hepatic status and, consequently, of portal circulation, but further study is needed.

CONCLUSIONS

There is a statistically significant reduction in spleen size in patients with HCV-related compensated cirrhosis who obtained SVR after treatment with DAAs and this can be used as a sensitive imaging marker to assess improvement in cirrhotic patient's condition.

NEWS

THE ENDOMETRIOSIS EFFECT ON OVARIAN MALIGNANCY AND ITS IMPLICATION IN GRANULOSA CELL TUMORS

Even if endometriosis is considered a benign pathology, it may play an essential role in ovarian cancer developing. There are data about the endometriosis effect on ovarian cancer but it is a lack regarding its involvement in granulosa cell tumor. Ashari et al. (2019) applied steroid-depleted serum or whole serum from endometriosis patients to the granulosa cells obtained from tubal or infertile women due to a male factor and used flow cytometry and quantitative real-time polymerase chain reaction in order to establish the expression level of inflammatory and apoptotic genes and also the apoptosis level of granulosa cells. The study shown that the granulosa cells which went under treatment with steroid depleted serum from patients with endometriosis presented a considerable increase expression of NFkB/RelA and AKT compared with control group. On the other hand, the genes related to apoptosis had a lower expression in treatment group compared with the control but also the synthesis of saturated fatty acids whereas the levels of unsaturated fatty acids were increased. The implication of steroids on endometriosis is contradictory and the sex hormones and cortisol levels may be modified due to this pathology, leading to alteration of the condition progression. Thus, decreased level of sex hormones in endometriosis females may be considered as a decisive risk factor for granulosa cell tumor (Asghari S, Dizajeykan AV, Ahmadi M et al. Evaluation of ovarian cancer risk in granulosa cell treated with steroid-depleted endometriosis serum: role of NF-kB/RelA and AKT. *J Cell Physiol* 2019; 234(7): 12011-12018).

MODIFICATION OF BIOCHEMICAL AND BIOLOGICAL PARAMETERS IN URINARY TRACT INFECTIONS IN ELDERLY

MODIFICATION OF BIOCHEMICAL AND BIOLOGICAL PARAMETERS IN URINARY TRACT INFECTIONS IN ELDERLY (Abstract): **Aim** To determinate the biochemical and microbiological tools for diagnosing urinary tract infections in elderly patients hospitalized at the "Sf. Parascheva" Clinical Hospital of Infectious Diseases, in Iasi, from January 2018 to June 2019. **Material and methods:** A retrospective analysis of the hospital - based medical records of the patients aged over 65 years diagnosed with urinary tract infection who presented signs and symptoms of UTI and urocultures were positive. The parameters followed were age, sex, place of residence, presence of comorbidities, duration of hospitalization, laboratory data. **Results:** We included in our study 387 patients over 65 years old which presented clinical manifestations of UTI. The highest frequency was in the age group 65-74 years. *Escherichia coli* was the most isolated pathogen (63%) followed by others as follows *Proteus, Klebsiella, Enterobacter, Pseudomonas*. **Conclusions:** Antibiotic resistance of uropathogenic strains isolated revealed that the highest resistance was found to Ampicillin followed by Fluoroquinolones and Cephalosporins**. Keywords**: BIOCHEMICAL MARKERS, AGING, UROCULTURES, ELDERLY, LABORATORY DIAGNOSIS.

Frequently found in adults age 65 and over, urinary tract infection (UTI) represent an important fragment of the amount of work in clinical microbiology laboratories (1). UTIs are the most frequent community and nosocomial acquired infections, accounting for considerable morbidity and health-care expenditure (2, 3).

The effects of aging make UTIs in the elderly hard to detect and hard to cure. The classic symptoms of a UTI are burning pain at urination associated frequent urination, but in elderly we may not found these symptoms. Instead, the aged population, mostly those presenting dementia, may encounter behavioral symptoms which can include confusion (4).

Seniors are susceptible to UTIs for many reasons. For example, their immune system is usually weak and can`t fight rapidly multiplying bacteria (5), and that, increases susceptibility to any infection. In addition, impaired cognitive skills and lower energy levels are concerns that determinate decreased self-care capacity and development of bacteria in elderly patients too (6). Many other medical conditions can increase the susceptibility to urinary tract infection in people over 65 years old, like diabetes, immobility, complications from medicines, and

problems emptying the bladder completely (7). Also, the elderly may experience more than one episode of UTI. Recurrent UTI have been liked as a potential cause of primary biliary cirrhosis (8, 9).

As a result of physiologic modifications corelated to aging and associated pathology, asymptomatic bacteriuria (ASB) is a common manifestation in older ones (10). This for, the diagnosis of UTI is challenging and may require particular diagnostic criteria than the standard ones. As a consequence of this factors doctors often depend on a few laboratory tests to sustain clinical suspicions and to determinate the cause of the infection and/or to provide isolates for antimicrobial susceptibility tests. Therefore, it is not surprising that the laboratory investigation of urine samples represents a substantial proportion of the workload in laboratories (1, 10).

Mainly, the cases of UTI have as etiological agent Gram-negative bacteria, including *Escherichia coli, Proteus mirabilis, Klebsiella spp., and Enterobacter* species (11). Fungal UTIs are not very common compared with the bacterial one . The risk of a fungal infection increases in patients with indwelling catheters, those that are suffering from diabetes, or who received recent antibiotic treatment (12).

A global threat is represented by the rising incidence of resistant or multi drug resistant uropathogens that require rapid diagnosis and initiation of antibiotic therapy with caution (12). Antimicrobial resistance can appear by mutation of the bacteria or by horizontal gene transfer. We can take as example the resistance that is provided by the naturally evolved β-lactamase genes which grant extensive resistance to β-lactams such as penicillins and cephalosporins (13).

MATERIAL AND METHODS

Studied patients

This is a retrospective study on biochemical and microbiological tools for diagnosing urinary tract infections in the elderly, performed at the "Sf. Parascheva" Infectious Diseases Clinical Hospital, in Iasi, from January 2018 to June 2019. The inclusion criteria for the present study were patients aged over 65 years admitted to the clinic, who presented signs and symptoms of UTI and urocultures were positive (bacterial confirmation $\geq 10^5$ CFU / mL).

Data collection

The parameters followed were age, sex, place of residence, presence of comorbidities, duration of hospitalization, laboratory data, including the etiological spectrum of the disease. The data were collected from the observation sheets. Given the fact that is a retrospective research, the consent was not necessary as long as the anonymity of the participants was respected (name, document, medical chart).

The urinalysis and the urine culture were performed in the hospital's microbiology laboratory. Urinalysis is performed on a sample of urine, test that find and/or quantify several elements in the urine sample, such as byproducts of normal and abnormal metabolism, cells, cellular fragments, and bacteria. For urine culture, the urine sample is cultured on agar plates for growth, concentration, identification, and isolation. The diagnosis of urinary tract infection requires the presence of bacteria $\geqslant 10^5$ CFU per milliliter of urine.

The diffusimetric method was used on the Mueller Hinton agar, used for antibiotic susceptibility testing. After 18 hours, the sensitivity of the germ can be assessed, depending on the diameter of the inhibition zone that appears around the antibiotic tablet. The correlation between the diameters of the inhibition zones and the sensitivity of the germ was made by comparison with the existing data in the tables of EUCAST (European Committee on Antimicrobial Susceptibility Testing) standards. And the results are expressed in sensitive,

resistant, and intermediate (14, 15).

RESULTS

During the above-mentioned period were hospitalized in the clinic 4,075 patients age 65 and over, 833 (20.44%) presenting clinical manifestations of UTI, either at the first examination or during hospitalization for another medical problem. Of these, 387 patients were enrolled for the current study. The highest frequency was in the age group 65 - 74 years (49.6%), with a predominance of cases in women (66.9%) and at those in the urban area (58.4%).

TABLE I

Characteristics of patients

	N	%
Mean age (years)	73 ± 5	
Sex (M/F)	128 / 259	
Rural/urban area of residence	226 / 161	
History of previous UTI	32	8.26
Presence of comorbidities	345	89.1
Healthcare facility-onset (HO) UTI	159	41.08

The duration of hospitalization was significantly longer (9 days *vs*. 5 days; p <0.05) compared to patients with urinary tract infection but unidentified pathogen.

Regarding clinical diagnosis, in our studied group only 39 patients had asymptomatic bacteriuria, the diagnosis being made after routine analysis. The other patients showed signs and symptoms of urinary tract infection, 189 patients at admission in the clinic and 159 patients during their hospital admission for other medical problem (tab. I).

The presence of nitrites in the urine also indicates a UTI which was found in 197 (50.9%) patients (tab. II) .

TABLE II

Analyzed laboratory variables

	N	%
Pyuria	326	84.2
Nitrites	197	50.9
$>10^4$ CFU	387	100

In the present study the prognosis of the disease was affected by the presence of comorbidities (n = 345; 89.1%) -diabetes (23,4%), hypertension (22,6%), acute kidney failure(20%), benign prostate hyperplasia (5,4%), chronic kidney disease (4,6%) and relapses (n = 32; 8.26%).

In our study group, laboratory investigations revealed plurimicrobial flora (82 urine cultures detect concomitantly infection with two different bacteria, 28 cultures with three types of bacteria). Statistically significant data were obtained for gram negative bacteria (77%). *Escherichia coli* was the most isolated pathogen (n = 244; 63%). Other uropathogens: *Proteus, Klebsiella, Enterobacter, Pseudomonas.* As causative pathogen, were identified also *Enterococcus spp* in 64 (16.5%) patients. and *Candida spp* in 25 (6.4%) patients. Urinary infections caused by *Candida spp.* are considered to be caused by frequent and long-term use of antibiotics. A number of 43 strains of *Enterobacteriaceae* were beta-lactamase releasing (28 *E. coli* and 15 *K. pneumoniae*).

Antibiotic resistance of uropathogenic strains isolated revealed that the highest resistance was found to Ampicillin (74.1%), followed by Fluoroquinolones (51.1%) and Cephalosporins (34.1%). Uropathogenic *E. coli* showed low resistance levels to Nitrofurantoin, Amikacin, and Gentamycin.

DISCUSSION

It is well known that on people over 65 years may be associated comorbidities, such hypertension, diabetes, or other pathologies in the urological sphere. Men with UTI are suffering from low urinary tract conditions, such as benign prostate hyperplasia, prostate cancer, urethral strictures and in female patients, pathology such as urinary stress incontinence, pelvic organ prolapse it is frequently encountered (16). Also, UTI can be encountered in patients that suffers from different other pathologies (e.g., leptospirosis) which can require urinary catheterization (17,18)

In order to establish a positive diagnosis for UTI we need to check out for the presence of clinical symptoms and then the next step is represented by laboratory examination. We start by collecting urine samples for biochemical examination, looking out for nitrites and leukocyte esterase, in order to detect the possible presence of bacteriuria and pyuria. But, in case of decreased urine concentration, or in the case of non-nitrite-producing bacterium (*Enterococcus spp.* and *Staphylococcus spp*. for example), the colorimetric dipstick may give us false-negative results (14, 15, 19, 20). Because of this reason in the majority of health-care settings, urine dipstick tests are no longer utilized the urine analysis at the point of care but in the clinical laboratory, where standardized readouts and expended microscopic urinalysis can be performed (21). The clinical and paraclinical data described above should be completed with urine culture. This test is performed in the microbiology laboratory where the urine sample is cultivated on agar-agar plates for growth, concentration, identification, and isolation. Are considered positive, urine cultures containing bacteria that exceed the threshold of $\geq 10^4$ CFU/mL whether we are talking about a single isolated bacterium or several (22). If the bacterial flora is dominated by non-*E. coli Enterobacteriaceae* species, for the identification of uropathogenic strains an additional phenotypic characterization of the isolated bacteria is needed. This investigation is regularly performed with automated systems based in the clinical microbiology laboratory. The results of a urine culture take between 18 to 30 hours (23, 24).

The bacterium was isolated and identified. What is next? The antibiogram. In order to determinate the microbial sensitivity. This investigation takes 24 to 48 hours more. Antimicrobial susceptibility testing (AST) is a procedure conducted as a phenotypic assay used to measure the pathogen growth in the presence of a specific or a group of antimicrobial agents. Once the results of antimicrobial susceptibility are available, they are divided into three categories: sensitive (S), intermediate (I), or resistant (R). According to standardized guidelines (25, 26) .

The clinical diagnosis of UTI is essentially based on medical history (includes an evaluation of urinary tract symptoms, history of UTI or other urinary tract problems, family history and sexual history). Urine tests (urinalysis - visual exam, microscopic exam, dipstick test) are the second important element in diagnostic testing. The

gold standard for positive diagnosis in UTI is urine culture, with identification and isolation of the pathogen, completed by testing for drug sensitivity (7).

Urinalysis represents a valuable diagnostic tool, a qualitative and semi-quantitative test. It is always used for the evaluation of a potential UTI case. This test can detect bacteriuria and pyuria which are marks of inflammation (27). Pyuria, is defined as the presence of white blood cells (WBC >10 elements) or positive leukocyte esterase (28). In our study, it was found at a rate of 84.2%.

The definite diagnosis of a UTI and the initiation of treatment require further investigation. Performing a urine culture is essential and we must also consider the patient's medical history.

Regarding the treatment, for patients with uncomplicated urinary tract infection Nitrofurantoin was selected, due to high concentrations in the urinary tract, minimal impact on gastrointestinal flora and low propensity to resistance. For those with complicated UTI or with multiresistant Gram-negative bacteria we chose Carbapenems which have good penetrability and are broad-spectrum antibiotics that can be used as empirical treatment for severe sepsis that may have as a couse AmpC or ESBL-producing bacteria.

Old age is a complicated process and involves a number of changes. In the elderly, self-esteem drops to alarming levels. This may be due to repeated urinary tract infections or the presence of urinary catheters, which exacerbates depression, which any older person struggles. In those cases, the psychologist can help increase self-esteem and regain self-confidence (29).

CONCLUSIONS

In this study the main tool for the diagnostic of UTI was the uroculture. In most of the cases, the etiology of UTIs was microbial; sometimes even plurimicrobial, in certain circumstances co-infection with two or more bacteria. *Escherichia coli* remains the most commonly isolated uropathogens, followed by *Klebsiella spp., Pseudomonas aeriuginosa, Enterobacter spp., Proteus mirabilis and Enterococcus spp*. Urinary tract infections caused by *Candida spp.* are considered to be caused by frequent and long-term use of antibiotics.

A urinary tract infection in seniors can become quite serious and ultimately can lead to sepsis, which can become life-threatening. An unexplained alteration of the general condition, digestive disorders or an isolated fever in an elderly person draws attention to the disease. Therefore, it is important to treat UTIs in the elderly as soon as the symptoms appear. Prompt diagnosis and targeted therapy can prevent complications and shorten the hospitalization.

NO EVIDENCE OF A MORE AGGRESSIVE PATTERN OF HEPATOCELLULAR CARCINOMA AFTER DIRECT ACTING ANTIVIRALS-RESULTS FROM A SINGLE CENTER OBSERVATIONAL STUDY (Abstract): After great concerns were raised regarding a high incidence of hepatocellular carcinoma (HCC) after direct acting antivirals (DAAs) therapy in cirrhotic HCV patients, an avalanche of studies that debated this issue emerged, whose results highlighted also a more aggressive HCC pattern after DAAs. We aimed to assess the pattern and imaging features of HCC in patients with HCV-related liver cirrhosis after DAAs. **Material and methods:** This is a single-center case-controlled retrospective study in which we included consecutive patients with HCC and HCV-related liver cirrhosis admitted in our clinic between January 1st, 2016 and May 1st, 2018. **Results:** Sixty-nine patients with HCV-related cirrhosis and HCC were divided into 2 groups depending on the DAAs-treated or untreated status: group I included 15 patients that were previously treated with DAAs and group II included 54 naïve patients. Regarding the distribution of HCC, there were no significant differences between the two groups (73.3% of group I patients and 55.5% of group II had unicentric lesion, p=0.215). The tumor size was significantly higher in group II compared to group I, with 66.6% of patients in group I and only 29.6% of patients in group II that have a tumor size less than 3 cm (p=0.009). Supportive treatment without ablation was more frequent in group II (33.3%) than in group I (6.6%) (p=0.047). **Conclusions:** Our study found no evidence of a more aggressive behavior of HCC after DAAs treatment compared to naïve patients. Furthermore, the pattern of HCC after DAAs did not affect the access to curative treatment. **Keywords:** HEPATOCELLULAR CARCINOMA, DIRECT ACTING ANTI-VIRALS, AGGRESSIVE PATTERN.

Hepatocellular carcinoma (HCC) is the most frequent primary liver malignancy ranked as the second leading cause of cancer-related death, with increasing incidence rates worldwide (1). The developments from the past 10 years considerably improved the therapeutic management of HCC leading to extended access to thera-

peutic options that increase the life expectancy of patients with HCC, regardless of the evolutionary stage. However, HCC still remains an aggressive malignant tumor with a high rate of cumulative recurrence over 5 years (70%) after curative therapies (2). The prognosis of HCC is estimated based on imaging features of the tumor such as the number and size of the tumors and the presence of vascular invasion.

The risk for HCC in patients with chronic infection with hepatitis C (HCV) infection and liver cirrhosis ranges between 2% and 8% per year (2). According to WHO's Global Hepatitis Report, about 1% of the world population is infected with HCV and the subsequent liver disease due to chronic HCV infection represents a favorable environment for the development of hepatocarcinogenesis (3,4). Previous studies from the IFN era demonstrated a significant decline in HCC incidence in patients who achieved SVR, thus prospects regarding the ability of the new DAAs to prevent HCC occurrence after HCV clearance were promising (5). However, great concerns were raised when several studies published in the beginning of the DAA era reported a high occurrence and recurrence rate along with a more aggressive behavior of HCC after DAA therapy in cirrhotic HCV patients (6, 7). This led to an avalanche of studies that debated this issue, whose results tend to a reduced incidence rate of both de novo and recurrent HCC after achieving SVR with DAAs therapy (8-10). Still, a worrying aspect is the identification of a more aggressive HCC pattern after DAAs therapy which several authors have previously reported, but data concerning this issue is scarce. Recent studies which assessed the impact of DAAs on HCC, provided evidence of high tumor aggressiveness comprising an advanced Barcelona Clinic Liver Cancer (BCLC) stage and early vascular invasion (11, 12). These tumor features are associated with limited access to ablation therapy and thus, have a negative impact on survival rate.

We aimed to identify and characterize the changes in the pattern and imaging features of HCC developed after DAA therapy in patients with chronic HCV infection and liver cirrhosis, as well as the impact on HCC treatment decisions, compared to patients with HCC and HCV-related liver cirrhosis without previous antiviral treatment.

MATERIAL AND METHODS

This is a single-center case-controlled retrospective study in which consecutive patients with HCC and HCV-related liver cirrhosis admitted in a tertiary gastroenterology referral center from North-Eastern Romania, between January 1st, 2016 and May 1st, 2018, were included. All patients who presented during the same period were divided into 2 groups depending on the DAA-treated (group I) or untreated status (group II). All patients with other concomitant causes of liver disease such as autoimmune hepatitis, thesaurismosis, non-alcoholic fatty liver disease, HCV/HBV and HCV/HIV co-infection were excluded. The regimens used in treated patients were: Paritaprevir/Ritonavir, Ombitasvir and Dasabuvir (PrOD) in patients with HCV-related compensated liver cirrhosis and Ledipasvir/Sofosbuvir (LED/SOF) + Ribavirin (RBV) for 12 weeks, in patients with decompensated liver cirrhosis.

The HCC tumor pattern was evaluated in all patients and consisted of the quantification of the largest tumor dimension, HCC multiplicity, the presence of malignant portal vein thrombosis (PVT), and the al-

pha-fetoprotein (AFP) levels.

Statistical analysis

Data collected was statistically analyzed using *SPSS 20.0* (Chicago, IL, SUA). All tests were two-tailed with p-value <0.05 considered statistically significant. Continuous variables were expressed as mean ±standard deviation for normally distributed continuous data, and as median for non-normally distributed continuous data. Groups were compared using Chi square test or Fisher's exact test for categorical variables and using independent *t*-Student test or Mann-Whitney *U* test for continuous variables (depending on data distribution).

RESULTS

This study included 69 patients diagnosed with HCC and HCV-related liver cirrhosis, mean age 67.5±12.2 years, mostly males 53.6%. Thirty-eight (55.1%) patients had comorbidities such as arterial hypertension (42%), diabetes (18.8%) and obesity (11.6%). Most patients had decompensated liver cirrhosis (55.1%), with a mean CPT score of 7.4±0.25.

All study patients were divided into 2 groups, depending on the DAAs-treated or untreated status, as follows: group I included 15 patients with HCC and HCV-related liver cirrhosis who were previously treated with DAAs, whereas group II consisted of 54 patients who were admitted in the same period with HCC and HCV-related liver cirrhosis without evidence of previous antiviral treatment.

The majority of patients from group I were females (53.4%), with mean age of 65.1±9.8 years. The majority had compensated liver cirrhosis; 86.6% had Child-Pugh A class, whereas 13.4% only were decompensated (1 patient had Child-Pugh B and 1 patient Child-Pugh C) (tab. I).

TABLE I

Demographics and clinical characteristics in the study groups

Parameter	DAAs treated N=15 (Group I)	No DAAs N=54 (Group II)	p
Age (yrs.), mean ± SD	65.1±9.8	68.1±12.8	0.397
Male, n (%)	7 (46.6)	30 (55.5)	0.541

AST (UI/L), mean ± SD	37.1±25.1	70.4±13.5	**0.028**

Abbreviations: IQR, interquartile range; SD, standard deviation;
FIB4, Fibrosis-4 Index for Liver Fibrosis; APRI, AST to Platelet Ratio Index.

Eleven (73.4%) patients were previously treated with PrOD and 4 (26.6%) patients received LED/SOF+RBV. SVR rate in the studied patients in group I was 100% and was defined by undetectable HCV-RNA at 12 weeks after end of treatment (EOT).

Patients in group II were predominantly males (55.5%), with similar mean age as group I (68.1±12.8), but with a higher percentage of decompensated liver cirrhosis than group I (Child-Pugh score was 5.9±1.4 in group I *vs.* 7.8±2.1 in group II, p=0.002). With respect to liver function, hepatocytolysis was more significant in group II compared to group I (ALT: 112.2 IU in group II *vs.* 41.6 IU in group I, p= 0.049; AST 70.4 IU in group II *vs.* 37.1 IU in group I, p=0.028). Also, APRI score was higher in group II compared to group I (p=0.004).

Regarding the distribution of hepatic focal lesions, there were no significant differences between the two groups (73.3% of group I patients and 55.5% of group II had unicentric lesion, p=0.215) (tab. II). The tumor size was significantly higher in group II compared to group I, with 66.6% of patients in group I and only 29.6% of patients in group II that have a tumor size less than 3 cm (p=0.009). AFP level was higher but not statistically significant in group II with a median (IQR) value of 78 ng/mL (1617.4) compared with a median (IQR) value of 8.4 ng/mL (32.7) in group I (p=0.059).

TABLE III

Tumor characteristics in the studied patients

Parameter	DAAs treated N=15 (Group I)	No DAAs N=54 (Group II)	p
AFP, mean ± SD	163.1±42.1	602.8±84.1	0.059

Lymph node metastasis, n (%)	1 (6.66)	13 (24%)	**0.031**

Abbreviations: IQR, interquartile range; SD, standard deviation; PVT, portal vein thrombosis.

An aggressive tumor pattern was established based on the identification of malignant adenopathy in 1 patient and malignant PVT in 2 patients from group I, and in 13 and 24 patients, respectively in group II, with a statistically significant difference between the two groups (p=0.031 and p=0.028, respectively). None of the studied patients developed another distant metastasis. According to BCLC classification, the majority of patients in group I were in stage A (33.3%) and B (40%), whereas patients in group II were approximately equally distributed in all stages (A-27.7%, B-24.1%, C-25.9%, and D-22.2%). With respect to Milan criteria, 6.6% of patients from group I and only 35.2% of patients from group II were within the criteria

(p=0.029).

Aggressive pattern of HCC had its impact on therapeutic decision. Supportive treatment without ablation was more common in group II (33.3%) than group I (6.6%) (p=0.047). Otherwise, TACE was the most frequent choice followed by surgery in both groups. One patient (1.8%) from group II had liver transplant.

DISCUSSION

Although there is a high amount of data regarding HCC occurrence and recurrence after DAAs, few reports assessed the behavior of HCC and the access to curative therapy after DAAs treatment. Data from our study emphasis important findings regarding the behavior of HCC after DAAs therapy compared to naïve patients. The incidence rates of HCC in patients without previous antiviral therapy seems to be related to the severity of cirrhosis considering that the mean APRI score was lower among DAA-treated patients with HCC than in naïve HCC patients. Furthermore, patients from group I had a higher percentage of compensated cirrhosis than those from group II (86.6% *vs.* 33.3%, p=0.001).

Recent studies which evaluated the behavior of HCC after DAAs, have found more aggressive features of HCC. For instance, a recent article by Fayoume *et al.* found that multiplicity and infiltrative patterns were more common in DAAs-treated HCC patients compared to naïve HCC patients (13). Another study revealed that malignant PVT and lymphadenopathy were significantly more frequent in DAAs-treated HCC patients (14). On the contrary, we found a more aggressive behavior of HCC among untreated patients from group II compared to group I. Although the lesions were predominantly unicentric in both groups, we found that malignant PVT and lymphadenopathy were more frequent in group II than in group I. Furthermore, patients from group I met the Milan criteria more frequently and had smaller sizes of tumor lesions than those from group II. According to BCLC classification, we found no significant differences between the two groups. Similarly, Fatima *et al.* reported that the pattern of HCC did not differ between patients treated with IFN-based therapy and those DAAs-treated, considering BCLC stages, multiplicity, malignant PVT and lymphadenopathy (15).

The best supportive care was the only recommended line of treatment for 6.6% patients from group I and for 33.3% patients from group II. The significantly higher percentage of patients from group II that received only best supportive care reflects the limited access to therapy based on BCLC classification. Access to curative therapy by surgical ablation was better in group I *vs.* group II, although TACE and sorafenib were the next most frequent options in both groups.

CONCLUSIONS

Our study found no evidence of a more aggressive behavior of HCC after DAAs treatment compared to naïve patients. On the contrary, we found a better access to HCC curative therapy in this group compared to untreated patients. Based on these findings, the screening of HCC in patients with HCV-related liver cirrhosis remains necessary after achieving viral clearance with DAAs therapy. According to current guidelines, abdominal ultrasound and AFP monitoring every 6 months in HCV-related liver cirrhosis seems the most appropriate strategy for these patients.

IMPACT OF OBESITY ON SKIN DISEASES (Abstract): Obesity is a chronic disease recognized as a global epidemic; however, the impact of obesity on the skin has received minimal attention. The aim of the study was to evaluate the skin diseases of aggravated by overweight. **Material and methods**: We conducted a retrospective study of 100 patients admitted in 2019 to the Dermatology Clinic of the Iasi "Sf. Spiridon" County Clinical Emergency Hospital. Of these, 79 adults had BMI above the healthy range. Moreover, the obese patients were divided into 4 BMI classes: overweight (28%), grade 1 obesity (27%), grade 2 obesity (16%) and morbid obesity (8%). **Results**: All participants underwent dermatological examination for the detection of skin diseases. This article describes the most common skin diseases associated with obesity: skin infections (43%), superinfected skin ulcers (37%), xerosis (23%), plantar hyperkeratosis (10%), worsening of psoriasis (9%), atopic dermatitis (6%), rosacea (4%) and acne (1%). **Conclusions**: Our study confirm that there is a high prevalence of different skin pathologies in overweight and obese patients. **Keywords:** OVERWEIGHT, OBESITY, BODY MASS INDEX, SKIN DERMATITIS, SKIN INFECTIONS.

Obesity, a serious global health problem, is nowadays the most common nutritional disorder in Romania, with a continuous rise in incidence (1).

The impact obesity on the skin and sebaceous and sweat glands is alarming, it being responsible for circulatory and lymphatic changes. Common obesity-related skin manifestations are acanthosis nigricans, keratosis pilaris, plantar hyperkeratosis, decreased skin mechanical strength, and increased sebum production. Also, obesity is associated with an increased incidence of bacterial and *Candida* skin infections, as well as with onychomycosis, inflammatory skin diseases, psoriasis, and rosacea (2).

The global epidemic of obesity results from a combination of genetic susceptibility, increased availability of high-energy foods and decreased need for physical activity in modern society. Obesity should no longer be regarded just as a cosmetic problem that affects certain individuals, but as an epidem-

ic that threatens global wellbeing (3).

In this article we will focus on obesity-associated skin, metabolic and physiologic changes.

MATERIAL AND METHODS

We conducted a retrospective observational study which included 100 patients with various diseases admitted to the Dermatology Clinic of the "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, in 2019. For each of these cases included in the study the following data were collected: sex, weight, height, body mass index, cholesterol, triglyceride and blood sugar levels, blood pressure and associated diseases.

RESULTS

Obesity, defined as a BMI (weight divided by squared height) higher than or at least equal to 30, influences both morbidity and mortality in the society. In the first table is presented the distribution of all the studied patients, according to the BMI - related categories, respectively 51% of the studied patients were obese.

Of the total number of obese patients admitted to our Dermatology clinic during 2019, 55% were women.

TABLE I

Distribution of study patients according to BMI

Category	BMI, kg/m^2	%
Normal weight	18.5 – 24.9	21
Overweight	25.0 – 29.9	28
Grade 1 obesity	30.0 – 34.9	27
Grade 2 obesity	35.0 – 39.9	16
Morbid obesity	> 40	8

Formula: BMI=kg/m^2 / BMI= body mass index

TABLE II

Distribution of patients with skin diseases according to BMI

Skin disease	Overweight (%)	Grade I obesity (%)	Grade II obesity (%)	Morbid obesity (%)
Skin infections	9	40	14	37
Ulcer	38	28	24	10
Xerosis	41	35	18	6
Plantar hyperkeratosis	0	30	30	40
Psoriasis	29	21	29	21
Atopic dermatitis	33	67	0	0
Rosacea	0	50	50	0
Acne	0	100	0	0

A strong correlation was found between obesity and severity of psoriasis. As shown in first figure, 9% of the overweight and obese study patients had moderate to severe psoriasis vulgaris, as well as psoriatic arthritis. In these patients the outcome was unfavorable on both topical, systemic, as well as biological therapies measured by

quality-of-life questionnaire.

Of the total overweight and obese study patients approximately 23% were diagnosed in addition to other conditions with xerosis cutis. Of these 35% had obesity grade I, 18% grade II, 6% morbid obesity, and the remaining 41% were overweight.

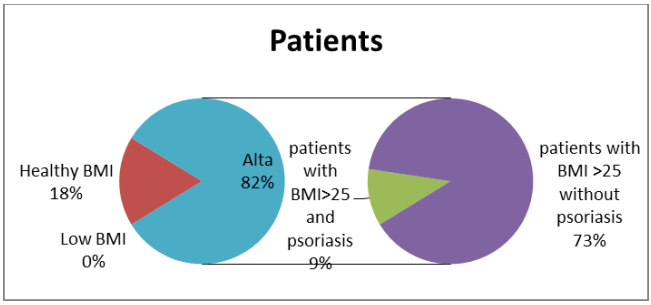

Fig. 1. Patents with obesity and psoriasis. Patients, Healthy BMI, Low BMI, patients with BMI > 25 and psoriasis, patients with BMI > 25 without psoriasis

DISCUSSION

Obesity causes various changes that affect skin barrier integrity, such as xerosis and increased *Trans Epidermal Water Loss* (TEWL). Xerosis is a common finding in patients with high BMI because of the change in *stratum corneum* hydration (4, 5).

In a study in which overweight and obese children were clinically assessed and TEWL was calculated, Massimiliano *et al.* (6) demonstrated that TEWL was significantly higher in those with high BMI. Obesity increases the TEWL rate, suggesting that due to the thick layers of subcutaneous fat obese patients sweat more profusely (7).

Another study conducted in 2017 (8) examines the influence of excess weight on skin hydration. The results suggest that overweight and obesity could promote water loss at the skin level, reflecting a particular skin adaptation to weight gain.

Of the 79 patients with high BMI included in the study, 37% presented on admission superinfected ulcers of different causes and with different locations.

Obesity is associated with altered collagen structure and impaired wound healing. In obesity, collagen deposition does not match the increase in skin surface, resulting in decreased skin mechanical strength. Leptin promotes wound healing, and obesity is associated with increased leptin resistance, thus contributing to the pathological wound healing process (9).

The main cause of superinfected ulcers was chronic venous insufficiency (CVI). Of the 79 patients with high BMI included in this study, most of them (41/52%) had this disease. Also, on admission the majority presented lipodermatosclerosis besides CVI and ulcer.

Obesity appears to be a major cause of microvascular dysfunction, contributing to the development of microangiopathy and hypertension, and this medical condition could adversely affect the clinical severity of chronic venous disease. Chronic venous insufficiency can result in varicose eczema and ulcerations. In addition, in resting state, the skin capillaries of obese patients are maximally recruited, with no functional capillary reserve, contributing to the development of ulcers (10).

A study conducted in 2002 by Danielsson *et al*. (11) investigated the impact of excess weight in patients with CVI and aimed at determining whether the effect can be explained only by the increased venous reflux. Patients with chronic venous disease were classified according to the clinical, etiological, anatomical and pathophysiologic system and BMI index. Most CVI patients were overweight (61%). It was demonstrated that patients with high BMI were more likely to present skin changes and ulcers ($p < 0.001$) than patients with a BMI < 25 kg/m^2, despite similar values for total reflux time ($p = 0.92$) and peak reverse flow velocity ($p = 0.98$). Overweight seems to be an independent risk factor for the increased severity of skin changes in patients with chronic venous disease (11).

The prevalence of plantar hyperkeratosis in the obese patients included in the study was 10%. Although this percentage is not significantly high, this is one of the most common dermatological conditions encountered in people with high BMI, as demonstrated by many other articles. Palmoplantar keratodermas are a group of disorders characterized by abnormal thickening of the skin on the palms and soles. Plantar hyperkeratosis in a horseshoe pattern affects the heel, arch of the foot and toe and is associated with obesity. Excess weight changes the anatomy of the foot and transfers the high pressure on the bony projections of the sole, causing mechanical trauma (12, 13).

In 1999, Garcia-Hidalgo *et al.* (14) conducted a study in a dermatology clinic in Mexico and aimed at determining the prevalence of skin diseases in 156 obese patients. Plantar hyperkeratosis was the most common finding in obese patients. Excess weight carried by people with BMI > 25kg/m^2 determines the transfer of weight during the gait cycle to other foot areas, abnormal foot posture, increased pressure and friction over bony prominences, thus generating keratotic disorders. Thus, plantar hyperkeratosis should be considered a cutaneous stigma of severe obesity. This is probably a result of pressure directly related to overweight.

Obesity increases the risk of infectious diseases in general, skin infections included (15). Possible mechanisms for this predisposition are the association of obesity with a proinflammatory state, decreased cellular immunity, and pharmacological interactions with antimicrobial agents (12, 13).

The incidence of candidiasis, intertrigo, folliculitis, furunculosis, erysipelas, cellulitis, erythroses, onychomycosis and tinea pedis and corporis is increased in patients with BMI > 25 kg/m^2.

In this article we demonstrated the increased frequency of intertrigo among patients with obesity, this condition being detected in 6% of the study patients who associated increased BMI. Intertrigo is an inflammatory skin condition characterized by well-defined erythematous plaques, maceration and linear cracks associated with moderate itching located in the skin folds (genitocrural, submamar, axillary, intergluteal, retro auricular, interdigital).

Obese patients have larger skin folds and sweat more profusely, thus increasing friction and moisture and leading to maceration and inflammation (16, 17).

A study conducted in 2010 had shown that intertrigo is among the most common skin dermatoses associated with obesity (22.2%) (18). Another study on intertrigo in diabetic patients found that skin surface pH is higher in the inguinal folds of women with a BMI> 25 compared to women with a

BMI < 25 kg/m^2 (19).

The association between obesity and severe lower limb cellulitis was also reported in 4% of our study patients. The literature specifies that obesity, in addition to being an independent risk factor for erysipelas and its complications, also prolongs length of hospital stay, favors the recurrence of erysipelas after prophylactic treatment with penicillin (20).

Erythrasma, a superficial localized skin infection caused by *Corynebacterium minutissimum*, and a relatively a common finding in obesity, was present only in one study patient.

Obesity is also an important risk factor for onychomycosis. This disease is quite common among patients with increased BMI, in our study patients it being present in a significant percentage, namely 20% of those with overweight and obesity.

In another 2002 study conducted on 1000 patients, obesity was found to be one of the most frequent predisposing factors in people with onychomycosis (9). In addition, in 2011, researchers at a pediatric clinic aimed at determining the frequency of nail onychomycosis in diabetics and found a strong association with obesity (21).

There is a linear trend between severity of obesity and *tinea pedis*.

The skin dermatosis most commonly found in our study patients with increased BMI was the tinea pedis, both intertriginous and hyperkeratotic, which with an incidence of 43% far exceeded the presence other conditions.

A 2008 study aimed at determining the prevalence of tinea pedis in diabetic and nondiabetic population. Cultures have shown a prevalence of 40% in the diabetics, as well as the fact that diabetic patients may be susceptible to interdigital fungal infections at a younger age than those with normal blood sugar (22). Other authors showed that tinea pedis is one of the first five obesity-associated skin diseases, being favored by increased humidity and profuse sweating (23).

The severity of psoriasis was closely correlated with obesity. Systemic and biological therapy used in the treatment of moderate to severe psoriasis appears to be less effective in patients with higher BMI. This finding could be associated with the higher doses needed to treat these patients. There is evidence that progressive weight loss reduces the severity of psoriasis (9).

In 2009, Perez *et al.* (24) conducted a study to evaluate the effect of weight loss in obese patients with psoriasis. Significant improvements in psoriasis were found after weight loss, and the positive changes were maintained for 64 weeks. Also, in 2012 Gleison *et al.* (25) reached a similar conclusion in their study, highlighting a direct correlation between obesity measured by different parameters and severity of psoriasis.

Rosacea is a chronic facial skin disease, increasingly common nowadays. In our study patients we found that 4% presented on admission to the Iasi Dermatology Clinic erythematotelangiectatic rosacea and BMI > 30 kg/m^2.

Although no direct correlation between obesity and rosacea was found in many studies, Suyum Li *et al.* managed to demonstrate in 2017 in a series of 5249 patients with this condition that the risk of rosacea increases with the increase in waist and hip circumference, and the associations appear to be independent of BMI (26).

Of the 51 obese patients admitted tour clinic in September 2019, 6% presented and atopic dermatitis besides atopic stigmata. Although further research is needed to determine the temporal relationship be-

tween obesity and atopic dermatitis and to clarify causality, there are several studies in the literature that strengthen the relationship between this disease and weight gain.

A 2012 retrospective case-control study of 2090 adults concluded that obesity in people over 21 years was associated with atopic dermatitis and increased atopic asthma, but not with of nonatopic dermatitis, nonatopic asthma, atopic or nonatopic rhino conjunctivitis and food allergies (27). Also, the same authors had conducted in 2011 another retrospective study on a series of 414 patients with atopic dermatitis aged 1-21 years. They found that overweight in children is associated with an increased incidence of atopic dermatitis and that the disease was more severe when obesity occurred at age 5 and was present for over a 2.5-year period (28).

Of the total number of obese patients, only one patient had papulopustular acne lesions. However, there are studies that suggest that increased BMI is associated with a higher risk of acne compared to normal weight population. This suggestion is based on the fact that adipose tissue synthesizes testosterone, thus contributing to the hyperandrogenism observed in obesity. Furthermore, weight gain is associated with a decrease in female sex hormones and increase in circulating androgen blood level or vitamin D deficiency. In women, obesity is associated with polycystic ovary syndrome, which can cause hirsutism, menstrual disorders, hyper seborrhea and acne (9, 29, 30).

CONCLUSIONS

Obesity is responsible for changes in skin barrier function, sweat glands, lymphatics, sebum production, collagen function and structure, wound healing, macrocirculation and microcirculation.

Thus, in this article we have highlighted the association of obesity with the increased incidence of several skin diseases: neurosis cutis, difficult wound healing, chronic venous insufficiency, presence of ulcers, ochre and purple dermatitis, plantar hyperkeratosis, skin infection, worsening of psoriasis, and in fewer cases with rosacea, atopic dermatitis and acne.

SHORT-TERM ASSESSEMENT OF LIVER FIBROSIS REGRESSION IN PATIENTS WITH HCV GENOTYPE 1b - RELATED CIRRHOSIS AFTER SUSTAINED VIROLOGIC RESPONSE (Abstract): Several studies suggested a regression of liver fibrosis (LF) over time after successful therapy in HCV infected patients. The aim of this study was to assess the changes of fibrosis occurring after successful direct acting antiviral (DAA) treatment using transient elastography (TE) and FIB-4 score in patients with HCV genotype 1 b compensated cirrhosis. **Material and methods**: LF were evaluated by TE and FIB-4 at baseline, sustained virological response (SVR) and 12 months after end of treatment (EOT). LF regression was defined as an improvement of ≥ 30% in Fibroscan® score at follow-up compared to baseline. **Results:** There were 98 patients with HCV-related compensated liver cirrhosis who achieved SVR after DAAs, most female (65.3%), aged 60.64 ± 9.56 years. Overall, LF had a significant improvement with a median (IQR) regression of 4.5 (1.8-7.8) from baseline to SVR and 5.1 (2.5-8.65) from baseline to 12 months after EOT (p <0.001). Also, the FIB-4 score significantly decreased at SVR and 12 months after EOT, similar to LSM values [median (IQR) at SVR 2.27 (1.55-3.26) and 2.21 (1.51-3.28) at 12 months after EOT (p <0.001)]. **Conclusions:** We demonstrated that achieving SVR with DAA-based regimens was associated with significant improvement of liver stiffness measured by TE, and liver function monitored by FIB-4 index, but the regression of fibrosis must be constantly evaluated in dynamic thus further studies are warranted to confirm these findings in other populations. **Keywords:** CHRONIC HEPATITIS C, VIBRATION-CONTROLLED TRANSIENT ELASTOGRAPHY, FIBROSIS 4 INDEX.

Chronic hepatitis C virus (HCV) infection is a major health concern being the leading cause of liver cirrhosis with its complication, including hepatocellular carcinoma (HCC) (1). Data from WHO's Global Hepatitis Report shows that 1% of the world population is infected with HCV (2). Among all HCV genotypes, genotype 1 is the most common, accounting for 60% to 70% of the cases, while genotype 1b is

predominant in Europe, especially in Romania, with an estimated prevalence of 92.6% (3, 4).

After decades of suboptimal treatment of chronic HCV infection with interferon (IFN) - based therapies, with high rates of adverse events and approximately 50% rate of sustained virological response (SVR), the advent of direct acting antivirals (DAAs) represented a revolutionary breakthrough in the management of HCV infection, with good safety profile and SVR rates in real-life practice that exceed 95% (5-7).

Previously, some studies demonstrated the near-term and long-term histological benefit of a SVR after treatment for chronic HCV infection with IFN-based regimen (8, 9). However, as DAA has been applied just since 2011, the short-time usage of DAA limited our knowledge regarding the histological outcomes after SVR with DAA therapy and few related studies drew inconsistent conclusions (10, 11).

Given the insidious onset and progression of fibrosis which secondary leads to architectural impairment of the liver parenchyma with high morbidity and mortality rates, the assessment of the stage of liver fibrosis (LF) is mandatory in the management of chronic HCV infection, in terms of prognosis and therapeutic strategies. Evaluation of LF was initially performed by liver biopsy (LB) which was considered as the gold standard procedure for the assessment of fibrosis. However, LB is an invasive procedure with serious complications in rare cases, limited diagnostic accuracy that depends on the specimen's size, sampling error and intra- and interobserver variability (12). Therefore, a great number of methods for noninvasive assessment (serological or imaging) for diagnostic, surveillance and treatment monitoring methods to determinate LF, that avoid the risks of invasive procedures, have been developed (13).

Transient elastography (TE) is a highly accurate ultrasound - based technique, most widely used and accepted for the assessment of LF, with good sensitivity and specificity (14). TE uses ultrasound acquisitions to measure the speed of a mechanical shear velocity propagating wave through the liver which is directly related to hepatic tissue stiffness and is subsequently converted in kilopascals as a unit measure (15). This was the first ultrasound - based technique to measure the liver stiffness (LS) used in clinical practice and is currently recommended by the international guidelines for the evaluation of patients with chronic liver disease (16).

The fibrosis index based on 4 factors (FIB-4) is one of the many noninvasive serological tests developed to detect LF in patients with chronic HCV infection. The FIB-4 index is a publicly available formula consisting of age, aspartate aminotransferase (AST), alanine aminotransferase (ALT) and platelets, which has a higher accuracy in predicting advanced fibrosis or cirrhosis when compared to LB (17,18). Initially, FIB-4 was developed for patients who were coinfected with human immunodeficiency virus (HIV) and HCV, to predict cost-effective significant fibrosis. Vallet-Pichard *et al.* validated FIB-4 for predicting significant fibrosis in HCV patients using cut-off values of ≤ 1.45 and ≥ 3.25 with an NPV of 94.7% and a PPV of 82.1% to predict the presence of significant fibrosis (19, 20). Two recent studies which assessed the predictive value of noninvasive serological tests and elastography compared to LB, reported FIB-4 to be better

than other scores such as BARD, AST-to platelet ratio index (APRI), AST/ALT ratio, and as good as MRE for predicting advanced fibrosis in patients with NAFLD (21, 22).

The aim of this study was to assess the changes of fibrosis occurring after successful DAA treatment with noninvasive methods by analyzing LF measurements obtained with TE and FIB-4 index in patients with HCV genotype 1 b compensated cirrhosis, and to identify the risk factors associated with persistent elevated biomarker score and Fibroscan® related values after obtaining SVR.

MATERIAL AND METHODS

This study was a single center, prospective observational cohort study which included 98 consecutive patients with HCV genotype 1b compensated cirrhosis who achieved SVR after DAA therapy with paritaprevir/ritonavir, ombitasvir and dasabuvir (PrOD) for 12 weeks in the Institute of Gastroenterology and Hepatology of "Sf. Spiridon" County Clinical Emergency Hospital Iasi, from December 2016 to July 2017. For each patient, baseline demographics, clinical and laboratory data were recorded, and further data was collected during patient's visits at baseline, SVR and 12 months after the end of treatment (EOT).

The diagnosis of cirrhosis was based on clinical, biochemical, imagistic features of liver cirrhosis, a liver stiffness ≥ 12.5 kPa measured with Fibroscan® and a FIB-4 index ≥ 3.25. Exclusion criteria were co-infection with HIV or HVB, the presence of decompensated liver cirrhosis.

FIB-4 score was calculated following Sterling's formula (17): FIB-4 = Age (years) x AST (U/L)/platelet count ($x10^9$/L) x ALT $(U/L)^{1/2}$ (21). LF was categorized as nonsignificant, significant (≥F2 to ≤ F4) and cirrhosis (F4) as follows: <1.45, >1.45 and <3.25 and ≥ 3.25 respectively. A significant improvement of serological test represents a decrease by ≥1-degree METAVIR score class (23).

Liver stiffness measurement (LSM) was performed by using TE (Fibroscan®, EchoSens, Paris, France) at baseline, SVR and 12 months after EOT. For a valid interpretation, at least 10 valid measurements were required with an interquartile range median (IQR/M) <30% and a successful rate > 60% (24). The median of LSM was expressed in kilopascals (kPa) and cut-off values for fibrosis were as follows: (1) less than 7.1kPa for < F2, (2) from at least 7.1kPa to less than 9.5 kPa for ≥ F2, and (3) at least 9.5 kPa for ≥ F3, and at least 12.5 kPa for F4. More than 30% regression in LF, at SVR and 12 months after EOT, was considered a significant improvement (25).

This study was conducted in compliance with the Helsinki Declaration and was approved by the institutional review board. Written inform consent was obtained from all patients, at the start of the study.

Statistical analysis

Data were expressed as mean ± standard deviation, if normally distributed, and as median and interquartile-range (IQR), if not normally distributed. Friedman's test and Wilcoxon signed rank test were carried out to detect longitudinal differences between noninvasive fibrosis assessment and clinical characteristics during follow-up. A *p* value less than 0.005 was judged to be statistically significant. All the analyses were performed by using *IBM SPSS 19.0* statistical software package (IBM corp., Armonk, NY, USA).

RESULTS

Patient characteristics

We included 98 patients with HCV-related cirrhosis with DAAs-associated SVR. The baseline characteristics of all patients are summarized in first table. The mean age of the studied patients was 60.64±9.56 years with a female predominance (65.3%) and a body mass index [BMI (kg/m^2)] of 28.16±4.28. Thirty-four (34.5%) patients were IFN-based regimens experimented, 18 (18.36%) had diabetes and 55 (59.12%) had hypertension. Liver stiffness at baseline was 21.30 (16.9-27.1) kPa.

TABLE I

Patient characteristics

Variable	Baseline	SVR	12-month post-treatment
Age in years	60.64 ± 9.56	-	-
Female, *n* (%)	64 (65.3)	-	-
BMI (kg/m^2)	28.16 ± 4.28	-	-
HCV treatment - experienced, *n* (%)	64 (65.3)	-	-
Diabetes, *n* (%)	18 (18.4)	-	-
Hypertension, *n* (%)	55 (56.1)	-	-
Esophageal varices, *n* (%)	27 (27.6)	-	-
BMI (kg/m^2)	28.16 ± 4.28	28.00 ± 3.90	28.77 ± 3.85
Platelet (1000/μL)	155.74 ± 69.01	154.92 ± 62.47	171.96 ± 76.35
ALT (IU/L)	100.6 ± 75.96	39.62 ± 9.44	26.39 ± 16.31
AST (IU/L)	91.83 ± 61.88	34.14 ± 6.96	29.85 ± 14.35
GGT (IU/L)	87.46 ± 58.24	53.42 ± 9.33	43. 45 ± 49.77

INR	1.09 ± 0.10	1.08 ± 0.09	1.06 ± 0.07
Fibrinogen (mg/dL)	303.56 ± 66.36	311.09 ± 52.68	355.46 ± 42.37
Total cholesterol (mg/dL)	157.84 ± 36.84	174.09 ± 18.1	190.82 ± 38.55
LDL cholesterol (mg/dL)	97.09 ± 17.95	129.98 ± 25.88	125.40 ± 30.01
HDL cholesterol (mg/dL)	36.82 ± 5.68	41.38 ± 7.99	29.01 ± 6.67
Triglycerides (mg/dL)	106.79 ± 37.23	96.97 ± 22.63	121.13 ± 53
AFP (ng/mL)	15.82 ± 21.20	6.20 ± 5.89	5.46 ± 4.11
Albumin (g/dL)	4.12 ± 0.52	4.46 ± 0.39	4.50 ± 0.41
FIB-4	3.69 (2.19-6.02)	2.27 (1.55-3.26)	2.21 (1.51-3.28)
LSM (kPa)	21.30 (16.9-27.1)	16.45 (13.8-23.7)	15.65 (11.3-22.9)

Data are shown as mean ± SD, but LSM are expressed as median (interquartile range); BMI, body mass index; HCV, hepatitis C virus; ALT, alanine aminotransaminase; AST, aspartate aminotransaminase; GGT, gamma-glutamyl transferase; INR, international normalized ratio; LDL, low-density lipoprotein; HDL, high-density lipoprotein; AFP, α-fetoprotein; LSM, liver stiffness measurement

Laboratory data at SVR and 12 months after EOT

All patients showed a statistically significant decline in AST, ALT, GGT and AFP levels after treatment (tab. II). Albumin, total cholesterol and low-density lipo-

protein cholesterol levels significantly increased overall, while high density lipoprotein cholesterol level increased at SVR and recorded a significantly reduction at 12 months after EOT. Significant differences were recorded between baseline *vs.* SVR, SVR *vs.* 12 months after EOT, and baseline *vs.* 12 months after EOT (tab. II). Triglycerides and INR levels showed no significant improvement.

Fibrosis evaluation assessed by TE and FIB-4 score

Overall baseline median (IQR) of LSM was 21.3 kPa (16.97-27.1) using Fibroscan® (tab. I). At SVR, the median TE measurement was 16.45 kPa (13.8-23.7) and 15.65 kPa (11.3-22.9) at 12 months after EOT, with an overall median (IQR) regression of 4.5 (1.8-7.8) from baseline to SVR and 5.1 (2.5-8.65) from baseline to 12 months after EOT (p <0.001). Moreover, the LSM improvement is maintaining from SVR to 12-month post - treatment (p =0.021). LSM regression was found in 83 (84,6%) patients at 12 months after EOT evaluation. Subsequently, the primary outcome was obtained in 26 patients (26,53%) (p <0.001), which had more than 30% LSM decrease. Distribution of LSM over the time are showed in figure 1.

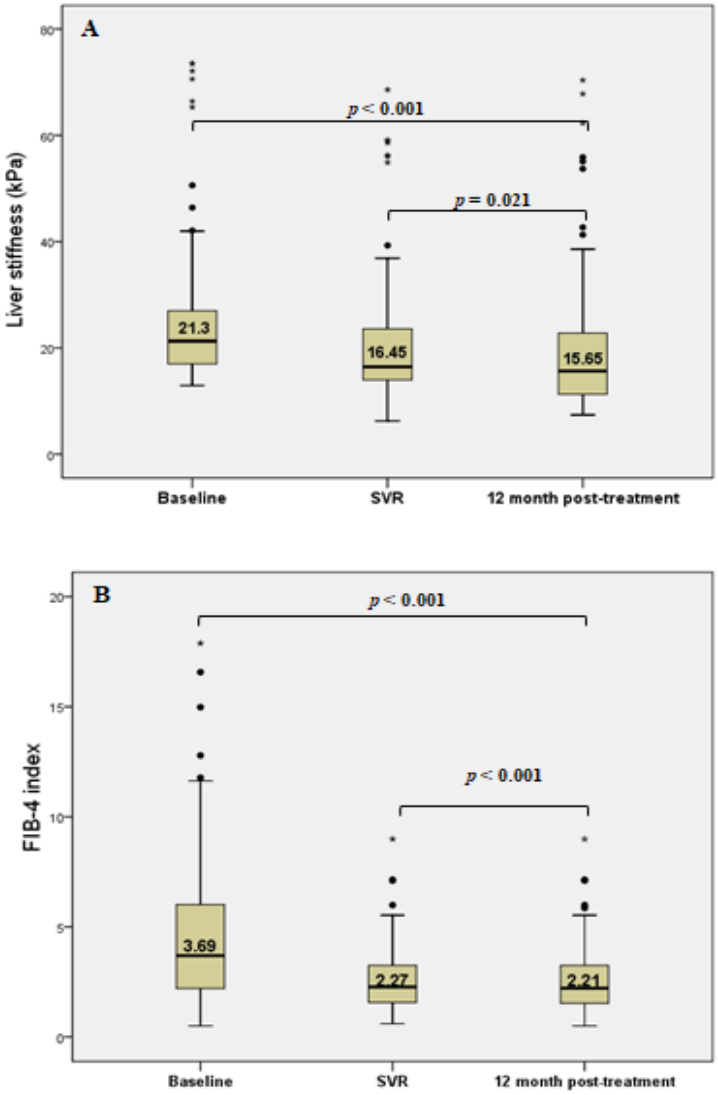

Fig. 1. Distribution of LSM (A) and FIB-4 index (B) over the time. The lines through the boxes represent the median score. The upper and lower bottom of each box represent the 25th and 75th percentiles, representing the interquartile range (IQR). The rest of the outliner observations are plotted as dots beyond the whiskers. Each bottom error bar ends at 1.5*(IQR) < Q1, while each top error bar ends at 1.5*(IQR) > Q3.

The FIB-4 score significantly decreased at SVR and 12 months after EOT, similar to LSM values (tab. II). At baseline, median (IQR) FIB-4 was 3.69 (2.19-6.02), while at SVR, the median (IQR) value reached 2.27 (1.55-3.26) with a decrease of 1.52

(0.37-2.75) (p <0.001). At 12 months after EOT, the median (IQR) was 2.21 (1.51-3.28), with a decrease of 1.52 (0.45-2.72) from baseline. The improvement of liver function expressed in FIB-4 score correlates with Fibroscan® METAVIR staging fibrosis. At 12 months after EOT, 73 (74.79%) patients had reached a downgrade of fibrosis stage from F4 (98) to F3 - F2 [(50)- significant fibrosis], < F2[(23)-nonsignificant fibrosis], while 25 remained at the same stage (F4).

In 13 patients there was a significant increase value of LSM median from 16.3 to 22.8 kPa while at 2 patients a stationary TE was reported. In this subgroup of patients median FIB-4 score was 2.43 from 4.3 initially, mean age 65 years.

DISCUSSION

Several previous studies conducted in the IFN era have shown a significant improvement of LF in patients with SVR (26-29). Given that DAAs have recently been introduced into the management of patients with chronic HCV infection, conclusive data on the LF dynamics after SVR are still scarce.

This study seeks to enrich the current literature by prospectively evaluating short-term LF changes after obtaining SVR with DAA-based therapies. The key finding of our study consists of the short-term improvement in liver function demonstrated by a significant improvement of LSM and FIB-4 score. In our study, at one year of follow-up, 83 (84,6%) patients achieved a significant LSM decrease from baseline while 26 (26.53%) had a significant improvement of LSM (more than 30% regression in LF). A similar rate of improving LSM and FIB4 score after SVR was reported by Mohammed *et al.*, with a 46% reduction of LSM assessed by Fibroscan® and a > 60% decrease of FIB-4 from baseline to one year (30). Another study which included patients treated with sofosbuvir-based DAA therapy, found a 31% reduction of liver stiffness after one year since EOT compared to baseline (31). In a prospective study, Chan *et al.* found a significant reduction in LSM after EOT in 49% of enrolled patients and, furthermore, a significant decline in LSM score with a median value of 1.4 kPa in patients with advanced LF (>9.5 kPa) (32).

Even if LB remains the gold standard for estimating LF, in the last decade, non-invasive methods for evaluating the degree of LF are tempting in clinical practice. Their repeatability and cost-effectiveness, besides patient convenience, represent sustainable arguments for abandoning LB in long-term evaluation of HCV cirrhotic patients. A partial regression of fibrosis ranging from 24% to 100% in patients with HCV-related liver cirrhosis who obtained SVR with IFN-based regimens was reported in literature (33). Accordingly, in a cross-sectional study by Hendenstierna *et al.* in which patients with SVR obtained with IFN-based regimens were followed-up through LSM for a period ranging from 5 to 10 years, concluded that the improvement of LF after viral clearance is significant in patients with pretreatment advanced fibrosis or cirrhosis, but with respect to long-term dynamics of fibrosis, regression becomes a slow process which at one point is stabilized (34). Therefore, the patients with more than 9.5kPa cut-off baseline value from their cohort had an improvement of LF. Only 21% patients remained with more than 9.5kPa at 10 years of fol-

low-up. Also, the authors reported a progression of fibrosis in 5% of the patients, correlated with an age ≥ 55 years and a BMI ≥ 25 kg/m^2. In our study, we found an increase of TE score in 13 patients, while 2 patients had a stationary value. Of these subgroups, the mean values of age, BMI and FIB-4 index after DAA treatment were 65 years, 30.9 kg/m^2 and 2.43, respectively. We tend to conclude that age and BMI values after treatment are risk factors for fibrosis progression, this data being in accordance with those reported by Hedenstierna *et al.* (34). In a retrospective study from Italy, the authors compared changes in LS during a long follow-up period of 5 years in 153 HCV patients treated with IFN-based therapy or IFN-free regimens, from which 36 had cirrhosis with baseline values of TE >12.5 kPa (35). First, the authors observed a significant regression in LS at SVR in patients who followed DAAs *vs.* IFN-based regimens. Secondly, a considerable decrease of fibrosis represented by a reduced proportion of cirrhotic patients compared to baseline was observed at EOT (20.5%), with a continuous declining trend over time (the proportion of patients with F4 was 9.8% at 1 year, 7.1% after 2 years, and < 5% after 4 years). Both these longitudinal studies concluded that after antiviral treatment, a rapidly regression of hepatic fibrosis is reached with improved liver metabolic function, but over time, especially after 1 year of follow-up, fibrosis regression tends to plateau.

Data from a retrospective study by Tada *et al.* showed an increase of total cholesterol, low density lipoprotein cholesterol, and triglyceride levels in patients with chronic HCV infection who achieved SVR with IFN-based regimens (36). Likewise, Hashimoto *et al.* reported similar changes in lipid levels in HCV patients treated with DAAs, with a much greater and rapid increase in serum low density lipoprotein cholesterol levels associated with regimen type and decreased HCV core protein levels (37). In our study, total cholesterol levels, high-density lipoprotein cholesterol levels, and LDL cholesterol levels changed significantly overall, thus concluding that viral clearance is closely related to lipid metabolism in patients treated with antivirals (37-39).

Our paper has some limitations. First, the small number of patients enrolled, secondly the lack of a LSM at EOT in accordance with FIB-4 score with variation range of TE (± 3 months). Thirdly, the short follow-up period represents a limitation because, for a true diminishing of liver stiffness, a longer follow-up period is required with a well-defined reevaluation-time. Fourthly, factors that are not HCV-related and might influence LSM such as alcohol consumption, steatogenic medication and lifestyle were not recorded.

CONCLUSIONS

TE was validated for assessing liver stiffness in patients with HCV-related liver cirrhosis, but long-term follow-up study based only on DAA based regimes treated patients are still limited. A rapid regression of fibrosis suggested by the improvement of LSM is secondary to the elimination of the hepatic inflammation after EOT. However, a dynamic assessment of LSM shows a tendency to settle on a constant value. In our patients, achieving SVR with DAA-based regimens was associated with significant improvement of liver stiffness measured by TE, and liver function monitored by FIB-4 index. A true regression of fibro-

sis must be constantly evaluated in dynamic, reason for which we intend to continue the TE follow-up of our cohort. Further studies are warranted to confirm these findings in other populations.

SILENT SINUS SYNDROME

The silent sinus syndrome represents maxillary sinus atelectasis that results in painless enophthalmos, hypoglobus and facial asymmetry and usually presents in the 3rd to 5th decade, without a gender predilection. Chronic occlusion of the maxillary sinus ostium results in gradual resorption of the air, negative pressure is generated within the sinus and gradual inward bowing of all four maxillary walls: roof, medial, posterolateral and anterior. Orbital volume increases with resultant enophthalmos and variable flattening of the malar eminence. Although the diagnosis is usually made clinically, imaging of the sinuses confirms the findings. CT demonstrates changes in the sinus and the adjacent structures. The sinus is fully opacified and reduced in volume with inward bowing of all four walls. The uncinate process is usually superiorly and laterally displaced, in direct contact with the inferomedial wall of the orbit and the ostiomeatal complex is occluded. MRI is not required for the diagnosis; it will demonstrate the anatomical changes and a sinus with thick, enhancing mucosa and secretions of variable intensity. Differential diagnosis includes: congenital maxillary sinus hypoplasia (which does not present with a developing facial deformity), post-traumatic maxillary sinus deformity, mucocele (expansion of sinus due to secretions), chronic sinusitis withmucoperiosteal thickening. THE INCIDENCE OF PEDIATRIC EYE INJURIES-BEFORE AND DURING THE SARS-CoV-2 PANDEMIC (Abstract): **The aim** of our study is to evaluate the incidence of the pediatric eye injuries during the non-pandemic and pandemic period and its impact on the patients' quality of life. **Material and methods**: The study included children who presented to the emergency department from January 2016 to December 2020. The following data were analyzed: age, sex, place of origin, type of injury therapeutic management, and hospitalization period and expenses. All patients were examined in detail including complete history and ocular examination. **Results:** 117 patients with eye injuries were enrolled in the study, being examined at the Ophthalmology Clinic of "Sf. Spiridon" County Clinical Emergency Hospital, Iasi between 2016 and 2020. Of the total study group, 32 children (27.4%) were under 5 noted as Group I, the remaining 85 (72.6%) were between the ages of 5-18, noted as Group II. According to the BETTS classification, an estimated risk for the following types of injury was identified for the age group 5-18 years vs 1-5 years: GD - penetrating 45.9% vs 40.6% and GI - contusion 28.2% *vs*. 18.8%. Associated systemic / ocular pathologies were significantly more common in the 5-18 age group. Depending on the eye injury, the length of hospital stay was indirectly correlated with visual acuity at discharge. The strongest correlation, although statistically insignificant, was between the length of hospital stay and the type of injury with lamellar laceration. In 69.1% of complex cases, the higher scores of costs were significantly correlated with the high length of hospital stay, and in 35.8% of cases without increased complexity. During the pandemic in 47.7% of complex cases, higher cost values correlated with the high length of hospital stay. In 67.2% of complex cases, the higher scores of costs were significantly correlated with the high length of hospital stay before the pandemic (2016-2019). In over 30% of children, the higher risk score was associated with the higher length of hospital stay. In over 26% of children, higher visual acuity at discharge was associated with a lower risk score. **Conclusions:** Severe pediatric eye injuries are a major cause of declining quality of life and one of the most common causes of ocular morbidity. Young children are more prone to injuries because of their natural curiosity to explore and their inability to avoid danger. **Keywords:** COVID-19, SARS-Cov-2, PEDIATRIC EYE INJURIES, OPEN GLOBE INJURY, BLUNT EYE INJURIES, CSIO, GLOBE RUPTURE, POST-TRAUMATIC QUALITY OF LIFE.

Pediatric eye injuries represent a serious concern for ophthalmologists, and it is estimated that between 20% and 50% of ocular injuries presenting to emergency occur in children (1). Most patients who have suffered eye injuries are blind to one eye, accounting for 8-14% of all injuries suffered by the child. Children are more prone to injury due to their inability to avoid danger. In general, men are more commonly reported to have eye injuries compared to women (2). Eye injuries have a significant impact on the patient's future quality of life, with children being at greater risk of amblyopia. SARS-CoV-2 is a highly transmissible and pathogenic coronavirus that was discovered in December 2019 in Wuhan, China. This virus has caused a pandemic of acute respiratory disease called COVID-19, which poses a threat to human health and public safety (3). The number of eye injuries reported in studies during the pandemic was contradictory. According to Pellegrini *et al.* there was a significant decrease in the number of eye injuries by 68.4% compared to the same period of the previous year in Italy. The authors found that daily activities changed during quarantine and were associated with a minimal risk of eye injuries (4). Another study by Hamroush *et al.* concluded that there is a higher risk of eye injuries occurring at home (5). According to these studies, traumatic eye injuries are largely accidental from an etiological point of view. Babies and toddlers suffer fewer injuries due to close supervision while older children injure themselves with toy tips, pencils, arrows, needles, thorns and stones (6, 7). The state of emergency was declared in Romania in March 2020, when the Ophthalmology Clinic of St. Spiridon Hospital was the only center in Moldova that was open and solved all the juries that were addressed to both surgically and medically. This paper analyzed both the number and type of injuries during the pandemic and before this period, as well as the functional prognosis related to the complexity of the case and the length of hospital stay.

MATERIAL AND METHODS

The Ophthalmology Clinic at "Sf. Spiridon" County Clinical Emergency Hospital, Iasi was the only ophthalmological clinic that hospitalized and treated all the ocular emergencies from Moldova region during COVID-19 pandemic. Our study included the cases that were addressed to the clinic between January 2016 and December 2020, including all children who presented with ocular emergencies. Inclusion criteria were all children aged 1 to 18 years, and all types of injuries (according to the BETTS classification). Patients who refused medical or surgical treatment, those over 18 and who did not show up for follow-up or did not cooperate in the evaluation were excluded from the study. For a better analysis and due to the low compliance of some categories, the children were divided into two age groups: Group I included the 1-5 years age group and group II the 5-18 years age group. The following data were analyzed: age, sex, place of origin, type of injury (according to the BETTS classification), associated pathologies, visual acuity, bio-microscopy of the anterior segment, therapeutic management, and hospitalization length and expenses. Those who met the criteria were considered complex: penetrating injuries, with or without CSIO (intraocular foreign body) and other associated systemic / ocular pathologies. In order to better appreciate the evolution of visual

acuity and the functional prognosis, a risk score that considered the type of injury, with or without CSIO, sex, age and environment was calculated. The highest score (i.e., 6) was given to the contusions (most frequent) and the lowest score (respectively 1) to the place of origin. This risk score was correlated with the complexity of the cases, the length of hospital stays and the visual acuity at discharge (tab. I).

Ethical Approval. During the study, the principles of the Helsinki Declaration were observed. Patients have signed an informed consent, which was attached to the observation sheets.

Statistical processing. The database was built in EXCEL and was statistically processed with the *SPSS 18.0*. These represent software for statistical and graphical data analysis, with an interface that helps the user to solve any need for experimental data processing. The statistical analysis of the data was performed with SPSS 18.0 and consisted of applying the following tests: ANOVA, Student t-test, F-test, ROC curve, linear regression analysis.

RESULTS

The study group consisted of 117 children with eye injuries, examined in the Ophthalmology Clinic of "Sf. Spiridon" County Clinical Emergency Hospital, Iasi between 2016 and 2020, the distribution by pandemic and non-pandemic years being similar in all five years of follow-up (figure 1).

The children's age ranged from 1 to 17 years. Of the total study group, 32 children (27.4%) were under 5 marked as Group I, the remaining 85 (72.6%) were aged between 5-18 years, noted as Group II. Of the total study group, 83 were male (70.9%), mainly in the 5-18 age group (56.3% vs 76.5%; p = 0.036).

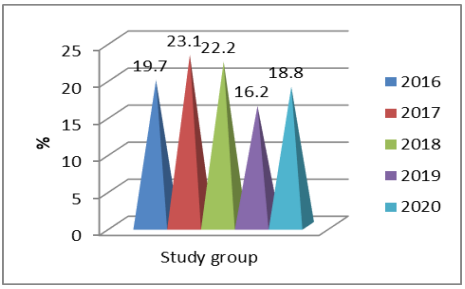

Fig. 1. Group structure by years of study

According to the results, 69 came from rural areas (59%), with no significant differences by age groups (53.1% vs 61.2%; p = 0.432). Associated systemic pathologies were significantly more common in the 5-18 age group (23.5 vs 6.3%; p = 0.02). Figure 2 shows the distribution of cases by sex and age groups and the place of origin.

The age of 5-18 years compared to 1-5 years was an estimated risk for the following types of injury: the prevalence of penetrating (45.9%) and contusive (28.2%) injuries. In the 1-5 age group, the higher frequency of GD-rupture was noted 6.3% vs 1.2% (OR = 2.53; 95% CI: 1.08-6.0; p = 0.150), but the result cannot be extrapolated to the general population. Depending on the eye injuries, the length of hospital stay was indirectly correlated with visual acuity at discharge as follows: in the case of GI contusion, the correlation was moderate, statistically significant (r = -0.405; r = 0,); in the case of GD CSIO, the correlation was moderate, statistically significant (r = -0.472; r = 0.038); in the other types of injury the correlation was moderate but statistically insignificant (figure 3). In 69.1% of complex cases, the higher scores of costs were significantly correlated with the high length of hospital stay (r = +0.691; p = 0.001), a significant aspect and in 35.8% of cases without increased complexity (r = + 0.358; p = 0.013).

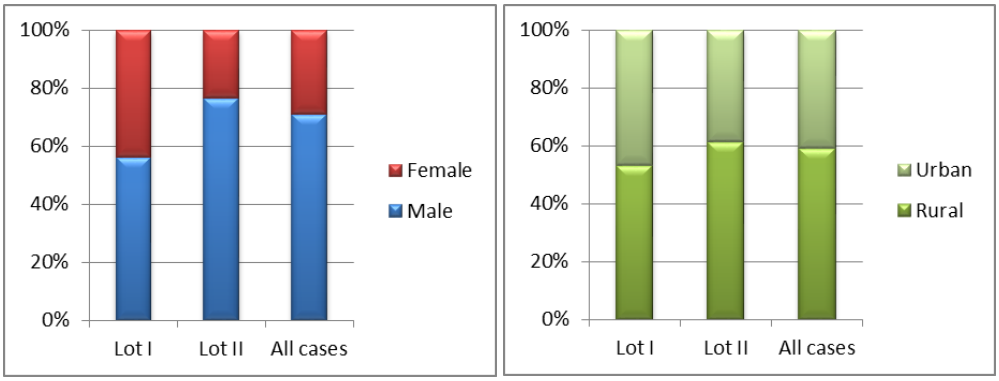

Fig. 2. a) Group structure by sex and age groups;
b) Group structure by place of origin and age groups

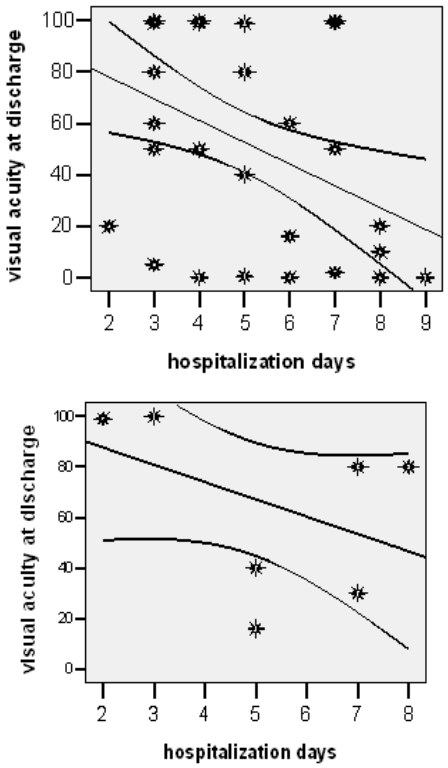

Fig. 3. The correlation of the length of hospitalization days with VA at discharge based on eye injuries

By analyzing the evolution of visual acuity according to eye injuries in group II (5-18 years age group) an increase in visual acuity at discharge vs. hospitalization in case of contusions and penetrating injuries was found. Since in group 1 (1-5 years age group) it was not possible to quantify the value of visual acuity, the calculation of a risk score that considered the type of injury, the presence or not of CSIO, sex, age

and place of origin was performed for both groups. The highest score (i.e., 6) was given to the contusions (most frequent) and the lowest score (respectively 1) to the place of origin. This risk score was correlated with the complexity of the cases, the length of hospital stays and the visual acuity at discharge. It was found from the statistics that males under 5 from the rural area, under medical treatment had an increased risk for a low functional prognosis (high risk score) (tab. I and fig. 1).

TABLE I

Descriptive risk score

Risk factor	Score
contusion	6
penetrating	5
CSIO	4
break	3
lamellar laceration	2
attached trauma	1
pliable	1
<6 y	1
Rural	1

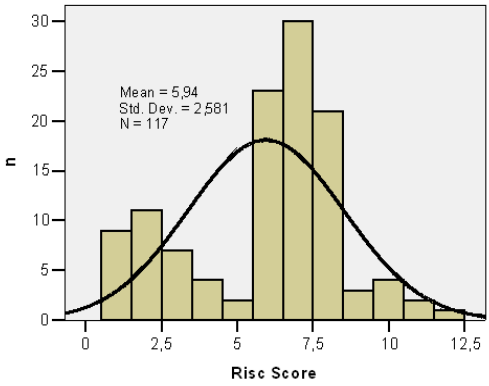

Fig. 4. Data and risk score histogram

According to statistics, a higher risk score was found in male children, in the 1-5 years age group, from rural areas and who were treated with medication *vs.* surgery. In over 30% of children, the higher risk score was associated with the higher number of hospitalization days (length of hospital stay) ($r = +0.308$; $p = 0.001$). The correlation between the risk score and the costs was direct, low in intensity, but statistically significant ($r = +0.247$; $p = 0.007$) (fig. 5).

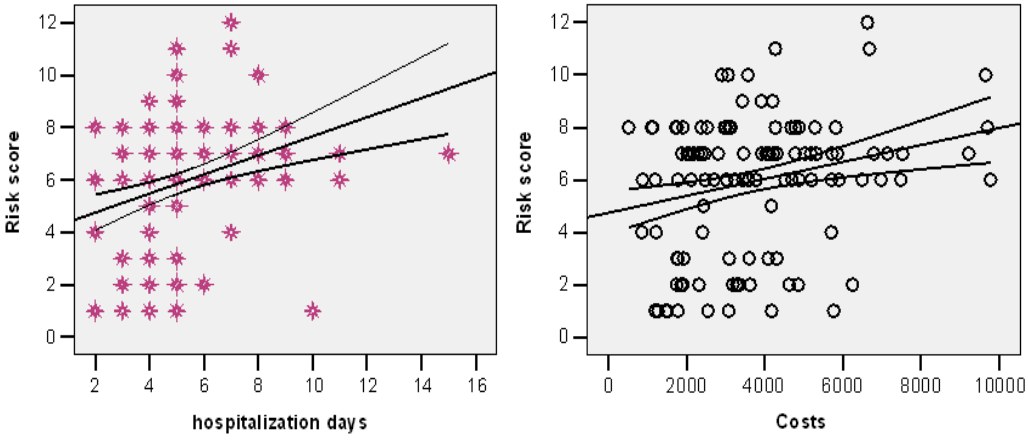

Fig. 5. The correlation between the number of hospitalization days (length of hospital stay), the costs and the risk score

In over 26% of children, higher visual acuity at discharge was associated with a lower risk score (r = -0.263; p = 0.004) (fig. 6).

Analyzing the ROC curve, age was an accurate predictor of an unfavorable prognosis (AUC = 0.703; IC95: 0.610-0.796; p = 0.001), while the age under 6 has a sensitivity of 83% and a specificity of 48% in predicting an unfavorable prognosis (fig. 7). Multiple linear regression analysis confirmed that no models that included significant dependence on eye injuries were found.

An analysis of the number of hospitalized and resolved cases during the non-pandemic years (2016-2019) vs. the pandemic year 2020 found that most cases were aged in the 5-18 range in a higher percentage, which was also noticed between 2016 and 2019 (81.8% *vs*. 70.5%; p = 0.268). During the pandemic (2020), in 47.7% of complex cases, the higher scores of costs were correlated with the large number of hospitalization days (high length of hospital stay) (r = +0.477; p = 0.164), an aspect noted in 37.6% of cases without high complexity (r = +0.376; p = 0.228). Before the pandemic (2016-2019), , the higher scores of costs were significantly correlated with the large number of hospitalization days (high length of hospital stay) (r = +0.672; p = 0.001) in 67.2% of complex cases, an aspect noted in 52.2 % of cases without high complexity (r = +0.522; p = 0.001).

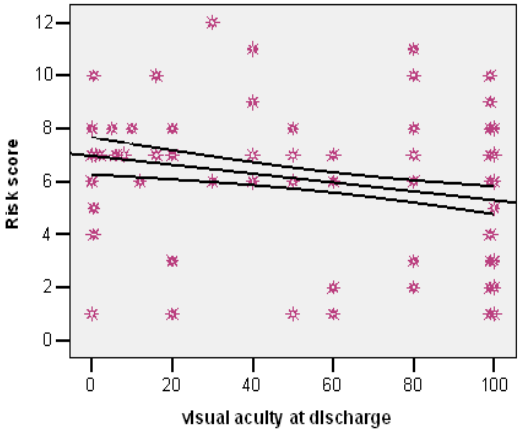

Fig. 6. The correlation between visual acuity at discharge and risk score

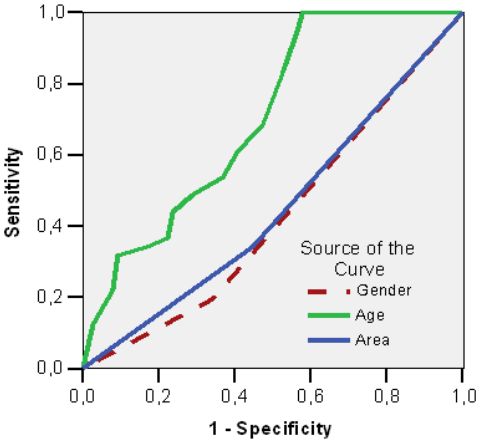

Area Under the Curve

Test Result Variable	Area	Std. Error[a]	Asymptotic Sig.[b]	Asymptotic 95% Confidence Interval	
				Lower Bound	Upper Bound

Fig. 7. ROC curve. Demographic characteristics predicting an unfavorable prognosis

DISCUSSION

One of the common causes of pediatric blindness is eye injuries (8). Compared to adults, children are more exposed to traumatic events due to their immature fine motor skills and curiosity, therefore adult supervision is a key factor in preventing eye injuries (9). The field of pediatric eye injuries assessment is quite broad and involves all practitioners who care for children, including the pediatrician, emergency physician, general and pediatric ophthalmologists. The American Academy of Ophthalmology (AAO) annually reports the results of the survey on the causes of eye injuries. These findings show common causes for injuries including missiles (20%), blunt objects (10%), body parts (i.e., fingers, fist) (12%), sharp objects (9%), and motor vehicle accidents (4%) etc. Other reports report unusual causes such as a rooster attack, pencil sharpening, microwave egg blasting, door handles, chopsticks, carbonated drinks and dishwashing detergent, (10). The assessment of an injured child should include the following steps: the extent of the injury should be determined quickly, without risking further damage to the eye, and the need for further examination with a subspecialist; the assessment of visual acuity should be tried and documented if the child is verbal and conscious; if the globe or eyelid is suspected to be affected, eye dressing, analgesic medication, tetanus immunization, and then the ophthalmologist contacted for further surgery (2, 6). Children over 5 are examined with Snellen's diagram and E diagram, the examination of the anterior segment is performed with the help of a direct ophthalmoscope, slit lamp; and the fundus with the direct ophthalmoscope or the biomicroscopy of the fundus (2).

SARS-CoV-2 is a highly transmissible and pathogenic coronavirus that was discovered in December 2019 in Wuhan, China. This virus has caused a pandemic of acute respiratory disease called COVID-19, which poses a threat to human health and public safety (3).

Strict isolation at home and other measures of social distancing have been applied to reduce the pressure on the health system. Although the Romanian government issued national isolation orders, the emergency ophthalmology department of our hospital continued to provide emergency ophthalmology consultations and care, due to the fact that it was the only hospital in Moldova that operated at the appropriate parameters during this period.

Pandemics can have an influence on the behavior of patients in seeking emergency medical treatment. The Emergency Department Syndromic Surveillance System: England (EDSSS) and the Royal College of Emergency Medicine, UK reported a decrease in the volume of patients during the first week of lockdown in the UK (11). In a study conducted by Pellegrini *et al*, a significant decrease in the number of ocular injuries by 68.4% compared to the same period of time of the previous year was discovered in Italy. The authors concluded that daily activities changed during the quarantine and were associated with a minimal risk of ophthalmological injuries. Because of the school closing, a decrease in the number of eye injuries was reported in children (4). Contrariwise, in a study conducted in the United Kingdom it was concluded that there was a higher risk for ocular injuries occurring at home (5).

In our study analyzing the cases managed during the non-pandemic (2016-2019) and the pandemic period (2020), we found a

similar number of hospitalized and resolved cases, most of the male cases from rural areas in the 5-18 years age group. According to the classification of injuries (BETTS), penetrating injuries were prevalent (52 cases-40.2%), followed by the contusive ones (30-18.8%), eyeball rupture, the presence of CSIO and other associated injury (28% - craniofacial injuries, eyelid wounds, post-traumatic cataract, secondary intraocular hypertension, retinal detachment). There has been a significant increase in visual acuity statistic at discharge vs. hospitalization (length of hospital stay). The number of hospitalization days was statistically significantly indirectly correlated with the visual acuity at discharge and hospitalization costs. In 47.7% of complex cases, the higher cost scores were correlated with the high length of hospital stay during the pandemic (2020). Although the number of cases during the COVID 19 pandemic was similar to previous years (2016, 2017, 2018 and 2019), health costs were higher in 2020 to prevent occupational exposure.

In order to better appreciate the evolution of visual acuity and the functional prognosis, the risk score achieved considered the type of injuries, the presence or lack of CSIO, sex, age, place of origin. It was statistically found that males under 5 from rural areas and under medical treatment had an increased risk for a low functional prognosis. In over 30% of children, the higher risk score was associated with the higher number of days in hospital. In over 26% of children, higher visual acuity at discharge was associated with a lower risk score. Similar studies used the ocular trauma score and prognosis of visual acuity (OTS) of Kuhn, ranging from 1 (worst injury and worst prognosis at 6 months of follow-up) to 5 (least severe injury) and the least severe prognosis at 6 months. Each score is associated with a set of predicted post-injury visual acuity. It has a predictive accuracy of about 80%, which means that the OTS will be accurate 4 out of 5 times. It shows the prognosis, but due to the impossibility of assessing visual acuity in some cases (non-compliant, and under 5), it cannot be used every time (12). Other studies that looked at the epidemiological features of the injury also showed a prevalence of male injuries, for the 6-11 age groups from rural areas. The increased hospitalization costs are directly associated with the complexity of the cases and the length of hospital stay (13, 14, 15).

In a recent study conducted at the same hospital for the pandemic period (March-May 2020), the analysis of the cases included in the study found that most were surgical (82%) and different types of injuries (wounds, contusions, foreign bodies), with a hospitalization period of approximately 6, 3 days and a duration of surgery of 45 minutes. The number of cases that were addressed was lower than 5.6 times for general hospitalizations and 77.6 times for 1 day of hospitalization, due to the restrictions regarding elective hospitalizations (cataracts, strabismus, etc.), practically during the emergency state only the pathology that needed to be surgically or medically resolved immediately was hospitalized (16).

STUDY LIMITATIONS

There are a number of limitations in this study. There is a retrospective study on a small number of patients. The first worth mentioning is the impossibility to quantify the visual acuity of the 1-5 years age group. There are not enough data on the evolution of visual acuity at 3, 6 months or one year after

the injury.

CONCLUSIONS

Severe pediatric eye trauma is a major cause of declining quality of life and one of the most common causes of eye blindness. Young children are more prone to trauma because of their natural curiosity to explore and their inability to avoid danger, but open injuries were prevalent in both age groups; Age under 5 years with a higher sensitivity and was a good predictor in the determinism of unfavorable functional prognosis. The low-risk score was associated with increased visual acuity and low hospitalization. The complexity of the cases has led to an increase in hospital days, costs and a reduction in patients' quality of life. Most cases during the pandemic and before the pandemic were surgical. Usually, the current management is based on the surgeons' professional expertise and will continue to be based on a retrospective review of the data gathered by the personal preferences of the attending ophthalmologist. The psychological burden of the associated visual impairment is of major importance, as it is known that one in ten children will have a permanent visual impairment.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

CRYPTORCHIDISM AND TESTICULAR CANCER - A LOOK IN THE PACIENTS FUTURE

Cryptorchidism is one of the most common congenital anomalies affecting new borns, and as a singular pathology or associated with other dysgenesis syndromes is one of the main factors of risk for the testicular tumors. Although a great number of cases of undescended testicles are diagnosed and treated during the first 6-12 months of life, there are rare cases of adults who are undiagnosed and untreated, with a high risk of malignancy. The article presents the case of a 50-year-old male with palpable tumor in right iliac fossa, with right scrotal sac empty. Clinical, imaging and laboratory findings suggests a seminoma in right undescended testis. Intra-abdominal mass in context of empty scrotum should alert for intra-abdominal testicular tumor. Adult with intraabdominal testicular tumor usually present at advance stage compared to intra-scrotal testicular tumor. Cryptorchidism needs to be managed preferably at 6 months for prevention/early detection of cancer. (Parajuli P, Pradhan M M, Chapagain S, *et al*. Intra-abdominal mass with empty scrotum in adult male. *Urol Case Rep* 2020; 34: 101451).

INVERTED PAPILLOMAS - UNCOMMON SINONASAL TUMORS

Inverted papillomas are rare (0.5-4.0%), benign sinonasal tumors, sometimes with malignant transformation, which affects middle-aged men (most frequently are seen in patients 40-60 years of age). The presentation can be similar to other sinonasal masses, with nasal obstruction, sinus pain and epistaxis. The lesions most commonly occur on the lateral wall of the nasal cavity, related to the middle turbinate, middle meatus and maxillary ostium. Radiography no longer plays a significant role in the assessment of sinonasal tumors. Computed tomography depicts a soft tissue density mass with enhancement; when the tumor enlarges, bone destruction and extension into the maxillary antrum, intralesional calcifications (residual bone fragments) are present in ~40% of cases; the location of the mass on the lateral wall of the nasal cavity is a clue for the correct diagnosis. On magnetic resonance imaging (T2 and contrast-enhanced T1 weighted images) the lesion has a convoluted cerebriform pattern. Differential diagnosis includes: sinonasal carcinoma (imaging does not distinguish between the two lesions), polyps, juvenile nasopharyngeal angiofibroma, olfactory neuroblastoma, paranasal sinus mucocele. INSIGHTS ON ADIPOKINES AND PHYSICAL ACTIVITY IN OBESITY PHENOTYPES (Abstract): Obesity activates multiple pathways of metabolic syndrome (MetS), therefore the balance between adiponectin and leptin, hormones that are secreted by adipocytes, is of great interest in better managing and understanding this complex disease. The aim of our study was to characterize obesity phenotypes by circulating levels of adipokines and insulin, followed by a better understanding of the influence a lifestyle modification, like physical activity, may have upon the values of these biomarkers. **Material and methods:** Our cross-sectional study included 104 patients organized in 4 groups, based on BMI and metabolic syndrome (MetS): metabolically healthy obese (MHO), metabolically unhealthy obese (MUO), metabolically healthy non-obese (MHNO), metabolically unhealthy non-obese (MUNO). Unhealthy phenotypes were characterized by the presence of MetS and obesity by a BMI $\geq$ 30 kg/m^2. All patients underwent insulin, adiponectin and leptin measurements, as well as MetS criteria investigations. After completion of the International Physical Activity Questionnaire, participants were graded with a low, moderate or high activity level. **Results**: All obesity parameters are significantly different between obese and non-obese patients, with leptin-adiponectin ratio (LAR) having the highest statistical power ($p<0.001$, $\eta^2=0.15$). Adiponectin, insulin, and HOMA-IR were statistically different between MHO and MUO, with no significance between MHNO and MUNO. Adiponectin levels are not significantly associated with a class that describes a specific physical activity level, whereas leptin levels are decreased in non-obese patients once they were more physically active ($p=0.042$). Relationship between physical activity level and obesity markers in obesity phenotypes did not conclude with any significant results. **Conclusions**: Adiponectin levels are higher in MHO phenotype than in MUO phenotype even though both groups present similar BMI means, therefore we can consider adiponectin a possible biomarker for metabolic syndrome in obese patients. Also, adiponectin, LAR, insulin, and HOMA-IR levels do not change in physically active patients, whereas leptin values decrease significantly in non-obese subjects that engage in physical activity. **Keywords:** ADIPOKINES, PHYSICAL ACTIVITY, OBESITY, METABOLIC SYNDROME, PHENOTYPES.

Metabolic syndrome (MetS) is a constellation of risk factors specific for cardiometabolic diseases, including abdominal obesity, atherogenic dyslipidemia, insulin

resistance, hypertension (1, 2). The pathophysiology of the MetS is not yet fully explained in the literature and it is still controversial whether each different criteria for the MetS stands for a specific pathology or they all fall under the same pathogenic process (2).

Obesity and even more important, abdominal obesity, activates multiple pathways of MetS, therefore adipose tissue serves as a key factor in the development of MetS (3, 4). The recently discovered endocrine function of the adipose tissue may explain some of the processes that occur in the MetS (5-7), emphasizing on the adipokines released that include hormones (e.g., leptin, adiponectin), peptides (e.g., apelin, resistin), inflammatory cytokines (e.g., interleukin-6, visfatin, omentin) (8).

Adiponectin and leptin are important adipocytokines secreted by fat containing adipocytes, which expresses contrasting effects. Leptin is reported to be directly proportional to obesity and body fat levels (9), reducing food intake and engaging energy expenditure while controlling insulin sensitivity and glucose levels (10). At the same time, leptin is associated with a higher proinflammatory immune response and higher risk of cardiovascular disease (11). In contrast, adiponectin is an anti-inflammatory, anti-atherogenic and anti-diabetic adipokine (12, 13), several studies reporting low levels in coronary heart disease, diabetes, hypertension (14-16). Therefore, the balance between these 2 adipokines is of great interest in better managing and understanding of obesity.

In the first part of our study, we analyzed circulating levels of adipokines and insulin in order to see if these may characterize a specific obesity phenotype and therefore explain pathogenic pathways in MetS. In the second part, we wanted to understand if lifestyle modifications may represent a therapeutic intervention in switching between these phenotypes, therefore we studied the influence of physical activity on adiponectin, leptin and insulin levels.

MATERIAL AND METHODS

Our cross-sectional study was conducted over a period of two years and included 104 patients organized in four groups: metabolically healthy obese (MHO), metabolically unhealthy obese (MUHO), metabolically healthy non-obese (MHNO), metabolically unhealthy non-obese (MUNO). Participants included in the study had no known chronic disease or had not followed treatment in the last 6 months for any cardiovascular or metabolic disorder and had no antecedent acute atherosclerotic pathology. The study was approved by the University Ethics Committee, number 1/27.07.2020 and all participants signed an informed consent before entering the study.

Baseline characteristics of the population

The following parameters were assessed for each patient: height, weight, abdominal circumference (AC), blood pressure, age, gender, residence, estimated visceral activity index (eVAI), along with the obesity and metabolic syndrome biochemical markers.

Blood pressure was measured after a 15-minute rest, with no prior caffeine consumption or no prior physical exercise engaged. A validated automated device and cuffs of 3 sizes were used, according to

arm circumference. Values were registered twice, and a mean value was considered.

Visceral adiposity index was calculated with previous validated equations (17):

$$\text{Men: eVAI} = \left(\frac{\text{AC}}{39.68 + (1.88 \times \text{BMI})}\right) \times \left(\frac{\text{TG}}{1.03}\right) \times \left(\frac{1.31}{\text{HDL} - \text{chol}}\right)$$

$$\text{Women: eVAI} = \left(\frac{\text{AC}}{36.58 + (1.89 \times \text{BMI})}\right) \times \left(\frac{\text{TG}}{0.81}\right) \times \left(\frac{1.52}{\text{HDL} - \text{chol}}\right)$$

A value of 1 is attributed to healthy subjects without obesity, with normal adipose tissue distribution, normal triglycerides (TG) and high-density lipoprotein-cholesterol (HDL-chol) levels.

Biochemical markers for obesity and MetS

All biochemical markers were measured in the same laboratory, using the same equipment and the same method during the entire study. Blood samples were collected by trained personnel after a 12 hrs. overnight fast in serum clot activator tubes and centrifuged in maximum 2 hrs, at 4^0 C and 4500 x g, for 10 minutes. Hemolyzed samples were excluded. For adiponectin, leptin and insulin measurements serum was stored in separate tubes at -20^0C. A specific requirement was addressed for insulin and prior to storage, blood samples were centrifuged in maximum 15 minutes after collection.

HDL-chol was measured using the direct method (elimination/peroxidase), TG using the glycerol phosphate oxidase method and glucose using the glucose-6-phosphate dehydrogenase method.

Quantitative determination of the adiponectin and leptin levels was performed using enzyme-linked immunosorbent assay (ELISA) kits supplied by Biovendor-Laboratorni medicina a.s., Brno, Czeck Republic: Adiponectin Human ELISA Competitive kit, CE-IVD, limit of detection 26 ng/mL, catalog number RD195023100 and Leptin Human ELISA, CE-IVD, limit of detection 0.2 ng/mL, catalog number RD191001100. Afterwards, leptin to adiponectin ratio (LAR) was calculated.

Serum total insulin concentration was measured using a solid-phase, enzyme-labeled chemiluminescent immunometric assay kit, Immulite 2000 Insulin, provided by Siemens (catalog number L2KIN2).

The homeostasis model assessment for insulin resistance (HOMA-IR) was calculated according to the report by Matthews *et al*. (18), using the formula: HOMA-IR = [insulin (μU/mL) x glucose (mg/dL)] / 405.

Obesity phenotypes

The four obesity phenotypes were established based on the metabolic and obesity status. Obesity was assessed at a BMI ≥ 30 kg/m^2 and metabolic syndrome criteria were as follows: glucose ≥ 100 mg/dL, HDL < 40 mg/dL (men) / < 50 mg/dL (women), TG ≥ 150 mg/dL, SBP/DBP ≥ 130/85 mmHg (19). Metabolically healthy status included participants with AC > 88cm (women) / 104 cm (men) and maximum 1 abnormal component from the metabolic syndrome criteria, while unhealthy status was established if patients presented a higher-than-normal AC and the metabolic syndrome (≥ 2 abnormal components).

Physical activity questionnaire

All participants in the study completed the International Physical Activity Questionnaire (IPAQ) in order to assess a physical activity level. IPAQ is a standardized self-report measurement tool that provides an estimate of physical activity and sedentary behavior for adults across a range of socio-economic settings (20, 21). Results were reported in categories (low/moderate/high activity levels) depending on the MET (metabolic equivalent of task), which represents the amount of energy expended carrying out physical activity. Activities reported by participants were quantified in METs according to the 2000 compendium of physical activities (22).

High activity was considered when any of the 2 criteria was met: (a) vigorous-intensity activity on at least 3 days and accumulating at least 1500 MET-minutes/week or (b) 7 or more days of any combination of walking, moderate-intensity or vigorous-intensity activities achieving a minimum of at least 3000 MET-minutes/week. Moderate activity was assessed if any of the 3 criteria was met: (a) 3 or more days of vigorous-activity of at least 20 minutes/day or (b) 5 or more days of moderate-intensity activity or walking of at least 30 minutes/day or (c) 5 or more days of any combination of walking, moderate-intensity or vigorous-intensity activities achieving a minimum of at least 600 MET-minutes/week. Individuals that do not meet criteria for moderate or high categories were considered inactive or with a low activity level (21).

Statistical analysis

Data analysis was performed using the *SPSS version 23.0* (IBM Corporation, USA) and Microsoft Excel 2003 (Microsoft Corporation, USA). Continuous variables were expressed as mean ± standard deviation (SD) and categorical values were expressed as frequencies (percentages). Continuous values between the obese and non-obese groups were compared using the t-test for independent samples. The same comparison between the 4 phenotypes was performed with one-way *ANOVA* test. Chi-square test was used for categorical comparisons. Eta squared (η^2) reports statistical power and a p value < 0.05 is considered statistically significant.

RESULTS

Baseline characteristics for the obese and non-obese groups are reported in Table I. Our study included more women than males per group, but the difference between groups was not significant, therefore excluding a possible bias to our research. Mean age was 57.86±8.21 for obese participants and 62.26±7.47 for non-obese participants. Biochemical markers involved in obesity that were measured in our study are all statistically significant between the 2 groups. The highest statistical power is observed for leptin-adiponectin ratio (LAR), suggesting that 15% variability in LAR is accounted for by the obese or non-obese category the patient is in.

We further analyzed the metabolic syndrome criteria, biochemical markers for obesity, eVAI and physical activity score for the 4 obesity phenotypes, according to metabolic health and obesity (Tab. II). Blood pressure, glucose, TG, HDL-chol were all statistically significant between phenotypes as expected since metabolic syndrome is one of the criteria for stratifying these phenotypes. At the

same time, we expected to see no statistically significant difference of obesity biomarkers between sub-groups of obese and non-obese, respectively, since BMI is very similar in the MHO and MUO groups and also in the MHNO and MUNO groups. Adiponectin, insulin and HOMA-IR were statistically different between MHO and MUO, with no significance between MHNO and MUNO. Adiponectin may be used as a biomarker for metabolic syndrome only in obese patients, reporting an 8% variability in adiponectin values that is accounted for by the metabolic syndrome status.

Our study also involved analyzing the relationship between physical activity and obesity biomarkers (Tab. III). Results report a significant decrease in leptin ($p=0.042$, $\eta^2=0.16$) as the person has a higher engagement in physical activities, only for non-obese patients (Fig. 1). We also observe a decrease in adiponectin levels for non-obese, but it is not statistically significant. In contrast, obese patients show slighter higher results for adiponectin, leptin, LAR (not statistically significant) when they perform moderate physical activity, followed by a decrease in a more active individual.

In addition, relationship between physical activity level and obesity markers in obesity phenotypes did not conclude with any significant results.

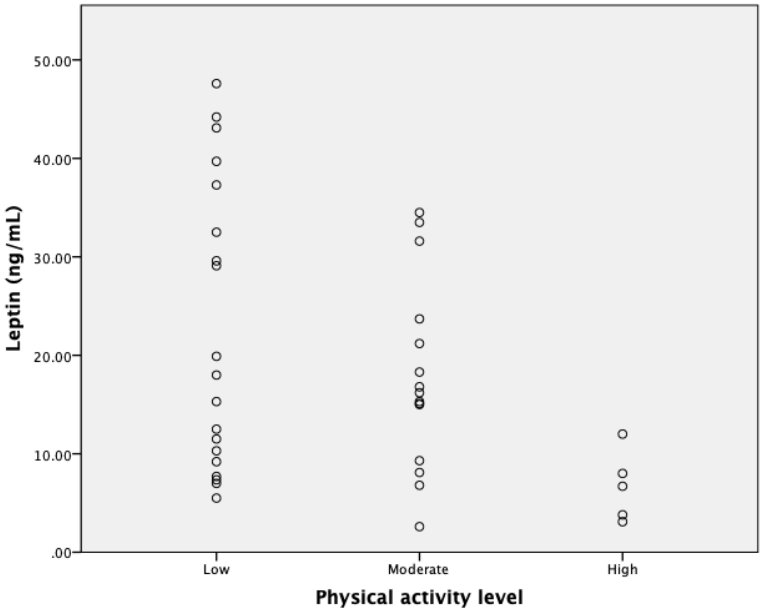

Fig. 1. Relationship between leptin levels and physical activity in non-obese patients

DISCUSSION

As more studies on a large scale are conducted, obesity phenotypes still represent a scientific controversial. MHO phenotype may be considered healthy, or it may just be one step before the unhealthy phenotype, therefore it is not clear if MHO remain healthy later in life or not (23). A recent study performed on 381,363 UK Biobank participants confirmed the healthier status of non-obese compared to MHO concerning heart failure and respiratory disease, but not concerning fatal atherosclerotic cardiovascular disease (24). Even if MHO phenotype is a transitory state, further investigating pathogenic processes engaged in these patients is essential to explain, prevent or even treat adiposopathy.

Our main finding in this study is that MHO have higher levels of adiponectin than MUO ($p=0.02$) even though both phenotypes report a very similar BMI mean (34 ± 3.68 vs. 34.96 ± 4.89, $p=0.437$). Other studies involving non-European descent individuals confirm the paradoxical hyperadiponectinemia in MHO phenotype (25-27) reported in our study, suggesting a protective role adiponectin might have in preventing metabolic syndrome. Interestingly, comparing MHO adiponectin levels with the ones for MHNO, which is considered a reference, the mean level of adiponectin slightly decreases in MHO, remaining at a very similar value to the one for MUNO ($p>0.05$). This proves that the secretion of adipokines is not affected as long as only one factor (obesity or metabolic syndrome) is present. Considering adiponectin's' anti-inflammatory effect, we can say that MHO have reduced inflammation compared to their MUO counterparts. Contrary to the above data, there are few scientific studies that report no difference between adiponectin levels among MHO and MUO individuals (28, 29).

The literature data concerning the inter-

connection between adiponectin and physical activity show contradictory results. A recent review stressed the importance of all variables that need to be considered for a more efficient interpretation of results: type, duration and intensity of exercise, but also age, gender, BMI and health status (30). There are studies that analyzed also genetic predisposition in the adiponectin gene as a possible contributor to a change in these values, even though no significant correlation was found (31). Plasma adiponectin levels seem to be negatively correlated with body fat percentage in males, but not in females (32), suggesting the presence of a possible gender-specific mechanism. Moreover, several studies involving aerobic interventions reported that adiponectin levels change independently from body composition changes, therefore changes in fat mass may be only one way to influence adiponectin levels and other mechanisms can link exercise to adiponectin levels (33-35). Our results noted no significant difference in adiponectin values between low, moderate or high levels of physical activity in obese or non-obese groups and not even among obesity phenotypes. Interestingly, the mean for adiponectin levels was almost identical in the obese group among low, moderate of high levels of physical activity ($p=0.999$), whereas in the non-obese group the values are lower once the subjects engage in more intense physical activity ($p=0.450$). We can conclude that for our population adiponectin levels are not significantly associated with a class that describes a specific physical activity level, but we do not rule out that there may be a change in values while performing acute physical training. Further studies need to clarify this aspect.

There was no significant difference among obese and non-obese concerning eVAI values, but the significance was present with high statistical power when we compared these values between MHO and MUO ($\eta^2=0.18$) or MHNO and MUNO ($\eta^2=0.23$). These results strengthen other findings in the literature that consider VAI a biomarker for MetS (36-38).

Leptin and LAR show no difference between the MHO and MUO, suggesting no association between these biomarkers and metabolic syndrome in our population. Our result may be explained by the development of "leptin resistance" in obesity, which includes mechanisms like negative regulation of ObRb (the long form of leptin receptor in mice) signaling in the hypothalamus, increased proinflammatory cytokine signaling in the brain or reduced transport of leptin across the blood-brain barrier (8). At the same time, of all the obesity biomarkers analyzed between obese and non-obese, the most significant difference was established by LAR, with 15% of variance in the value of this biomarker being accounted for by the inclusion in one of the 2 groups. The obese patients showed almost 2 times higher values than non-obese ones, confirming results from other studies (39-41).

A recent review extracted 107 effects from 72 articles regarding the relationship between leptin and physical activity and reported that chronic exercise training can effectively reduce leptin levels. There was no difference concerning plasma leptin decrease and the type of exercise (aerobic, resistance, concurrent exercise), intensity, frequency or duration. Even though body fat percentage is strongly associated with low leptin levels, chronic exercise training independently shows a decrease in leptin values, regardless of change in adiposity (42). Our results reported a significant

decrease in leptin levels in non-obese participants once they were physically more active. Interestingly, obese patients did not present changes in plasma leptin levels that were statistically significant. These results support the findings of a recent study that analyzed the influence of a 12-week physical activity program on leptin resistance in metabolic syndrome, which brought changes in most metabolic syndrome parameters, but not in leptins' plasma levels (43). On the contrary, previous studies showed a 22% reduction in leptin levels associated with a 7% decrease in body weight (44) or a 45% reduction in leptin levels associated with a decrease of 2.1 kg/m^2 in BMI (45). The small sample size or the subjective evaluation of participants' own physical activity through a questionnaire and not a specific program that is prescribed and followed up by trained specialists, may represent the reasons for not reporting a significant change in leptin levels in obese patients.

CONCLUSIONS

Adiponectin levels are higher in MHO phenotype than in MUO phenotype even though both groups present similar BMI means, therefore we can consider adiponectin a possible biomarker for metabolic syndrome in obese patients. Also, adiponectin, LAR, insulin and HOMA-IR levels do not change in physically active patients, whereas leptin values decrease significantly in non-obese subjects that engage in physical activity.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding the scientific research.

THE IMPACT OF ESBL-PRODUCING ENTEROBACTERALES: AN OLD STORY WITH NEW PERSPECTIVES (Abstract): Antibiotic resistance represents a global crisis, one of the biggest challenges that humanity is facing. In addition to the SARS-Cov-2 pandemic, we are currently witnessing another, more devastating pandemic of multidrug-resistant microorganisms, not only in hospitals but also in the community. **Material and methods:** we aimed to analyze the incidence and implications of urinary isolated, extended-spectrum β-lactamase-producing (ESBL+) *Enterobacterale*s, from patients admitted between 01/01/2018 and 31/12/2018. **Results:** the main identified pathogen was *Escherichia coli*, accounting for 67.3% of all cases; the ESBL-production rate was 26.5%, with *E. coli* and *Klebsiella pneumoniae* emerging as leading etiologies. Mean age was significantly higher for patients with ESBL+ isolates (57.6 *vs.* 65.1 years, $p<0.0001$), while urinary catheterization was more frequently associated with ESBL+ strains (21.8% ESBL+ *vs.* 6.2% ESBL-, $p<0.0001$). As anticipated, antibiotic susceptibility was significantly influenced both by ESBL production and urinary catheterization, except for nitrofurantoin and fosfomycin**. Conclusions:** comprehensive approach of the local antibiotic susceptibility profile can facilitate the choice of a proper therapeutic management, based on regional particularities of an East European country. **Keywords**: ENTEROBACTERALES, ESBL, ANTIBIOTIC-RESISTANCE, UTIs.

Extended-spectrum β-lactamase (ESBL) producing *Enterobacterales* have become a significant clinical and epidemiological concern. Those strains are associated with adverse patient outcomes, such as prolonged length of hospitalization and a higher risk for therapeutic failure. In 2017 alone, only in the United States were recorded more than 197,000 cases of infections caused by an ESBL-producing (ESBL+) microorganisms (1).

ESBLs are capable of hydrolyzing most broad-spectrum β-lactam antibiotics. Compared to infections caused by non-ESBL-producing (ESBL-) microorganisms, those caused by ESBL-producing strains tend to be more severe, with higher morbidity and mortality rates (2). However, these enzymes have a rather reduced capacity to hydrolyze carbapenems, thus they are typically required for the treatment of these infections, but carbapenem resistance is

also on an upward trend (3).

ESBL production is the most important mechanism that induces β-lactam resistance, with over 200 such enzymes described to date (4). The spread of ESBL-producing isolates is alarming, especially concerning the strains of *Escherichia coli* and *Klebsiella pneumoniae*; however, other members of the *Enterobacterales* family that produce such enzymes have also been identified (5).

Urinary tract infections (UTIs), whether community - acquired or healthcare-associated, are the most common infections caused by *Enterobacterales* (6). In the context of increasing antibiotic resistance among *Enterobacterales* isolates, the management of these infections has become increasingly challenging There are multiple studies analyzing the risk factors for UTIs with ESBL-producing *Enterobacterales* (3, 4). The most commonly incriminated risk factors are previous antibiotic use (within the last 3 months), especially third-generation cephalosporins (7), history of urinary tract infections, previous hospitalizations (within 3-6 months before the admission), urinary catheterization, age, prostatic hypertrophy, male gender; the presence of congenital abnormalities, urolithiasis, history of invasive urological procedures, or associated comorbidities such as diabetes mellitus. However, those risk factors are highly variable, not only at individual level, but also geographically influenced, therefore the outlining of a regional high-risk pattern is of utmost importance.

MATERIAL AND METHODS

We conducted a retrospective study, in which we performed an analysis of the incidence of positive urine cultures determined by an *Enterobacterales* strain, from 01/01/2018 to 31/12/2018.

Inclusion criteria were isolation of an *Enterobacterales* strain (*E. coli, K. pneumoniae, Enterobacter* spp. *Proteus* spp., *Serratia* spp., *Providencia* spp. or *Morganella* spp.) in urine cultures ($\geq 10^5$ colony-forming units/mL). Confirmation of ESBL production was achieved by the double-disc synergy method, which showed synergy between ceftazidime, ceftriaxone, cefotaxime, and amoxicillin discs with clavulanic acid on Mueller-Hinton agar plates.

Antibiotic susceptibility testing was performed using the Kirby Bauer disk diffusion method, using the EUCAST clinical breakpoints table v 8.1, for interpretation of minimum inhibitory concentrations (MICs) and zone diameter breakpoints (mm).

Cases *of Enterobacterales* colonization and those with CFU counts below the threshold value of 10^5/mL were excluded.

For data collection we used the records from the archive of the Microbiology Laboratory of the Infectious Diseases Hospital "Sf. Parascheva" from Iasi, from where we were able to extract data on certain demographic characteristics of the patients (age, sex), the presence of a permanent urinary catheter, and, most important, the etiological agent, the antibiotic susceptibility profile with the identification of ESBL-producing strains.

Statistical analysis was performed by using *SPSS Software version 23.0* (IBM, Armonk, VA, SUA) and *Microsoft Excel version 2013* (Microsoft Corporation, Redmond, WA, USA). A *p*-value of 0.05 was considered statistically significant.

RESULTS

During the analyzed period, we identified 742 positive urine cultures with an *Enterobacterales* strain. Of those, we found

a total of 197 (26.5%) urine cultures with ESBL-producing (ESBL+) *Enterobacterales*.

The most frequent etiological agent identified was *E. coli*, responsible for 500 cases, followed by *Klebsiella* spp. - 157 cases (of which 147 *K. pneumoniae*, 8 *K. oxytoca* and 2 *K. aerogenes*), *Proteus* spp. - 53 cases (*P. mirabilis* - 51 cases, *P. vulgaris* - 2 cases), *Enterobacter* spp. - 19 cases (*E. cloacae* - 4 cases, *Enterobacter* sp. - 15 cases), *Providencia* spp. - 7 cases (*P. stuartii* - 6 cases, *Providencia* spp. - 1 case), *Serratia* spp. - 4 cases *(S. marcescens* - 3 cases, *Serratia* sp. - 1 case) and *Morganella morganii* - 2 cases.

As expected, the most commonly ESBL+ isolate was *E. coli*, identified in 83 (42.3%) cases; the second position was occupied by *Klebsiella* spp., accounting for 76 (38.5%) cases, followed by *Enterobacter* spp. (14 cases – 7.1%), *Proteus* spp. (13 cases – 6.6%), *Providencia* spp. (7 cases – 3.5%), *Serratia* spp. (3 cases 1.5%) and *Morganella morganii* (one case – 0.5%).

We identified an association between patient age and infection with an ESBL+ strain, with 85.3% of the total number of patients aged over 50 years, while almost half, 43.2%, were aged over 70 years, with no significant differences by year (tab. I).

TABLE I

Age distribution

Age	ESBL + 197	ESBL - 545	*p*
≤ 30 years	10 (5%)	87 (15.9%)	0.0001
31 – 50 years	19 (9.7%)	85 (15.5%)	0.03
51 – 70 years	83 (42.1%)	206 (37.7%)	0.28
> 70 years	85 (43.2%)	167 (30.6%)	0.001
Mean age (years)	65.1	57.6	<0.0001

We identified an overall predominance of female patients, 512 (69%) *vs.* only 230 (31%) male patients. When assessing the gender of patients with an ESBL + isolate, we identified a milder difference, with only 104 (52.8%) females and 93 (47.2%) males, compared to 408 (74.9%) females and 137 (25.1%) males with an ESBL – strain (tab. II).

We identified 77 (10.3%) patients with an indwelling urinary catheter; of those 43 had a ESBL + strain (tab. III).

We also observed some variability concerning the etiology in patients with urinary catheter. Thus, the main identified agent for those patients was still *E. coli*, identified in 33 (42.8%) cases, followed by *K. pneumoniae* in 28 (36.3%) cases, *Proteus* spp. – 8 (10.4%) cases, *Providencia* spp. – 6 (7.8%) cases, *Enterobacter* sp. and *Morganella morganii*, one (1.3%) case each (tab. IV).

TABLE II

Gender distribution

Gender	ESBL + 197	ESBL - 545	Total	*p*	OR (CI)
Female gender	104 (52.8%)	408 (74.9%)	512	**<0.0001**	0.3755 (0.2672-0.5276)
Male gender	93 (47.2%)	137 (25.1%)	230		

TABLE III

Urinary catheterization

	ESBL + 197	ESBL - 545	Total	*p*	OR (CI)
Urinary catheterization	43 (21.8%)	34 (6.2%)	77 (10.3%)	**<0.0001**	4.1965 (2.5849-6.8128)

TABLE IV

The microorganisms isolated, in urinary catheterized patients

	ESBL + 43	ESBL -34	Total 77	*p*	OR (CI)
E. coli	9 (20.9%)	24 (70.6%)	33 (42.8%)	<0.0001	0.1103 (0.0389-0.3124)
K. pneumoniae	23 (53.4%)	5 (14.7%)	28 (36.3%)	0.0004	6.6700 (2.1710-20.4927)
Proteus spp.	5 (11.6%)	3 (8.8%)	8 (10.4%)	0.688	1.3596 (0.3010-6.1421
Providencia spp./ *Enterobacter* spp./ *Morganella morganii*	6 (13.9%)	2 (5.9%)	8 (10.4%)	0.249	2.5946 (0.4890-13.7666)

When analyzing ESBL + strains, we identified a worrisome susceptibility rate to aminopenicillins in combination with beta-lactamase inhibitors, the lowest being for *Klebsiella* spp. isolates (3.9% to amoxicillin+clavulanic acid and 6.5% to ampicillin + sulbactam).

]The most active beta-lactam identified (excluding carbapenems) was cefoxitin, with 63.4% of all strains sensitive to this antibiotic, with the highest percentage found in *E. coli* isolates (97.5%). We also identified high resistance for other antibiotic classes, notably fluoroquinolones, with only 11.1% sensitivity to ciprofloxacin, the lowest among *Klebsiella* spp. strains (6.5%). Sensitivity to aminoglycosides is preserved, especially for amikacin (58.8%), with the lowest percentages for tobramycin (22.8%) (tab. V).

TABLE V

In contrast, for ESBL- isolates, we identified significantly higher sensitivity rates, not only to beta-lactams, but also to all antibiotic classes (tab. VI).

Sensitivity to nitrofurantoin and fosfomycin was routinely determined only for *E. coli* strains, observing high susceptibility rates, but without notable differences between ESBL+/- isolates; For ESBL(-) strains we identified a 98.5% and 99.2% sensitivity to nitrofurantoin and fosfomycin, respectively. Concerning ESBL (+) isolates, we observed that 87.9 and 100% of them were sensitive to nitrofurantoin and fosfomycin, respectively.

In addition, we aimed to perform a comparative analysis of the sensitivity profile, according to the presence of an indwelling urinary catheter. Thus, we noticed that urinary catheterization was associated with significantly lower susceptibility rates, especially among *Klebsiella* spp. and *Proteus* spp. isolates (tab. VII).

DISCUSSION

ESBL-producing *Enterobacterales* represent a significant clinical issue, as it is very epidemiologically challenging. These strains are associated with adverse outcomes such as prolonged length of hospitalization, therapeutic failure, and increased mortality. Consequently, broad-spectrum antibiotics, (e.g., carbapenems), are typically required for the treatment of these

infections, but carbapenem resistance is also, on an upward trend, an aspect which was highlighted by our present study and previous work (8, 9).

The most commonly isolated etiological agent was *E. coli*, for both ESBL+ and ESBL- isolates, followed by *Klebsiella* spp. (the vast majority, 93.6%, is represented by *K. pneumoniae*). These findings are consistent with the majority of studies, which classify *E. coli* as the main etiology for both pediatric, adult, and geriatric UTIs (10-12).

We have identified a relatively small percentage of ESBL+ *E. coli* isolates, 16.6% (83 strains). Most studies have reported much lower rates (13), although we identified even more dramatic reports, generally from India, where incidence reaches up to 45% (14-16). This "borderline" pattern may be due to some socioeconomic particularities, Romania (and especially its Northeast region) exhibiting certain particularities from both developed and developing countries (17). A very recent study provided additional evidence concerning the relationship between low income or poor education and the increased risk of UTI (18).

Of course, the incidence of ESBL+ *E. coli* causing community UTIs differs notably, with a significant geographical variability; in China, for example, it ranges from 45.2 to 68.2% (19, 20), in Canada from 9.1 to 14.1%, and in the US from 6.5% in 2010 to 16.0% in 2014 (21, 22). For *Klebsiella* spp. we have identified a more dramatic ESBL production rate, 48.4%, with the highest carbapenem resistance associated.

Overall and somehow expected we identified notable prevalence of women, accounting for 69% of all patients, even though the percentage was significantly lower in ESBL + isolates (52.8% ESBL + *vs.*74.9% ESBL -, $p<0.0001$). This can be explained by the fact that the female gender, due to its associated anatomical particularities, is considered an additional, non-modifiable risk factor for the development of UTIs, regardless of the etiological agent, but especially among urinary catheterized patients (23, 24).

UTIs represent the fourth most common healthcare-associated infection (25). Although morbidity and mortality from UTI in urinary catheterized patients are considered relatively low compared to other healthcare-associated infections, the high prevalence of urinary catheterization use leads to a significant burden on the public health systems. It is estimated that between 15% and 25% of hospitalized patients are being urinary catheterized (26, 27), and, unfortunately, in many of these cases, the catheters are placed after an inappropriate indication (28, 29). In addition, for every additional day a patient has an indwelling urinary catheter, there is a 3-7% increased risk of developing a caUTI (1, 30, 31).

In our study, we observed significant differences while analyzing the microorganisms identified among patients with urinary catheterization. Thus, the main etiology is still represented by *E. coli*, responsible for 42.8% of the cases, most of those being ESBL-strains (70.6%), while the leading etiology of ESBL + caUTI is *K. pneumoniae*, accounting for 53.4% cases, *vs.* only 20.9% for *E. coli*. Most studies classify *E. coli* as the main etiologic agent of caUTI (24, 32), although we also found studies that reported *K. pneumoniae* as the most common *Enterobacterales* isolated (33, 34). In European countries, the incidence of caUTIs caused by ESBL + *E. coli* is generally less than 5% (7,35) but can be as high as 23.6% in Spain or 38.2% in Turkey (22).

A study conducted by Albaramki et al., which examined the incidence and impact of UTIs caused by ESBL+ *Enterobacterales* in the pediatric population, also reported increased rates of resistance to amoxicillin + clavulanic acid (94. 8%), third-generation cephalosporins (98.7%), fluoroquinolones (54.5%) or gentamicin (54.5%), while resistance to amikacin (32.5%) and especially to carbapenems (1.3%) remained at significantly lower percentages (36). Also, Vachvanichsanong *et al.* reported increased rates of resistance to cephalosporins (99-100%, except for cefoxitin, to which only 19% of isolates were resistant) or aminopenicillins (99%), but with much lower rates of resistance to fluoroquinolones (44%), piperacillin+tazobactam (22%) or amikacin (11%), while none of the isolates were resistant to carbapenems (37).

Another recent study from China, which assessed the antibiotic susceptibility profile of ESBL+ *E. coli* strains isolated from patients with community-acquired UTIs, showed increased resistance rates to common cephalosporins (93.4% resistance to cefotaxime, 93.1% to ceftriaxone, 76.8% to cefepime), while to cefmetazole they identified only 2.4% resistance or 8.1% resistance to the combination of cefoperazone and sulbactam. In addition, they reported very low resistance rates to amikacin (3%), nitrofurantoin (2.7%), fosfomycin (8.4%), or carbapenems (0.3% resistance to imipenem and 0.6% to ertapenem) (22). As in our study, resistance to fluoroquinolones (72.3%) or trimethoprim+sulfamethoxazole (68.7%) was identified in increased percentages (22).

This polymorphic and dynamic pattern of resistance and the resulting therapeutic challenges represent a solid argument for the constant, further research of UTIs in this area of Europe, already characterized by high rates of resistance.

CONCLUSIONS

The incidence of UTIs caused by ESBL+ *Enterobacterales* in the Northeast region of Romania is continuously increasing, especially among elderly and female patients. We have identified significant antibiotic resistance rates, especially when compared to ESBL- isolates, the levels observed for some antibiotics representing a serious epidemiological alert.

Antibiotic resistance caused by the production of ESBLs is limiting the currently available treatment options for UTIs caused by these pathogens. Given the lack of new antibiotic molecules, there is a valid rationale for sensitivity testing of older antibiotics that retain some activity against ESBL+*Enterobacterales*. Of these, fosfomycin or nitrofurantoin emerge as promising options due to their broad spectrum of activity against both gram-positive and gram-negative bacteria. Microbiological data seem to support this possibility, as susceptibility rates for strains of *E. coli*, the main etiological agent of UTI, are very high. However, further research is needed to ascertain these findings.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding the scientific research.

ETHICAL APPROVAL

The study was approved by the Ethics Committee of "Sf. Parascheva" Clinical Hospital of Infectious Diseases, Iasi, Romania.

POSTPARTUM HEALTH-RELATED QUALITY OF LIFE AND ASSOCIATED PERINATAL FACTORS AMONG WOMEN IN NORTH-EAST ROMANIA (Abstract): The aim of this cross-sectional study was conducted to assess the health-related quality of life and its affecting factors among women from North-East Romania at six weeks postpartum. **Material and methods:** The study was conducted in a tertiary care hospital, at the "Cuza-Vodă" University Hospital of Obstetrics and Gynecology in Iași (Romania), from May to December 2021. The validated short-form (SF-36) questionnaire was used to assess health-related quality of life (HRQoL) of 321 women at six weeks postpartum. **Results:** The mean Physical Component Summary and Mental Component Summary scores, two summary measures that aggregate the eight most important domains of health status, were both reported higher than 50% (59.05 ± 19.48, 55.08 ± 25.17, respectively). Highest median scores were reported in body pain (69.25 ± 28.87) and physical functioning domains (65.42 ± 14.78). Lowest median scores were reported in vitality (44.57± 20.20) and general health perceptions (48.73 ± 25.99). Factors associated with higher overall HRQoL were maternal age under 30 and multiparity. Number of days of peripartum hospitalization was inversely proportional to all scales of the SF-36 questionnaire. **Conclusions:** In this study, we highlight the need for additional studies on ways to predict the onset of labor, in order to shorten the period of peripartum hospitalization of pregnant women in North-East Romania, and implicitly to improve their quality of life**.** **Keywords:** POSTPARTUM, HEALTH-RELATED QUALITY OF LIFE, SF-36.

Nowadays, the increase in life expectancy has drawn attention to the concept of quality of life. Quality of life is a complex and subjective concept, a parameter considered by the World Health Organization(WHO) as a fundamental indicator of health. In the field of health, quality of life is a multidimensional concept that addresses issues such as the physical, mental, emotional, and social functioning of an individual (1). More specifically, the quality of life in medicine means the ability of pa-

tients to perform their usual tasks in their daily lives.

Women's subjective perception of their health-related quality of life (HRQoL) is essential for measuring the quality and effectiveness of maternal and child health programs. Although pregnancy, childbirth and puerperium are considered to be physiological conditions, they involve multiple changes on the physical, emotional and social level of the woman. There is also the risk of a series of comorbidities and complications, changing the woman's quality of life. As a result, health interventions are increasingly focusing on prevention and treatment. In addition, to reduce the incidence of comorbidities and complications, maternal and fetal health professionals strive to provide quality healthcare and a satisfying experience to patients during preconception, conception, pregnancy, childbirth, and postpartum, with the ultimate goal of improving women's HRQoL.

Traditional indicators used in statistics on health and quality of life associated with pregnancy and childbirth remain essential, but mortality and morbidity are considered inappropriate and defining, as the health associated with these periods should be assessed not only on the basis of saving lives, but also in terms of improving the quality of life (2).

The following instruments have been developed to measure the quality of life of women in postpartum period: Mother-Generated Index (MGI) developed by Symon *et al. (*2003); Maternal Postpartum Quality of Life (MAPPQOL); Postnatal Morbidity Index (PNMI), Maternal Adjustments and Maternal Attitude (MAMA) (3, 4). These questionnaires include different areas, such as: socioeconomic, psychological-spiritual, physical appearance, sexuality, relationship with partner/newborn/family and symptoms. Unfortunately, none of these measuring instruments have been translated, validated and used in patient studies in Romania. In the absence of such specific instruments, researchers use generic measuring instruments. The most widely used tool for measuring the quality of life of women in pregnancy and postpartum is SF-36. SF-36 includes multi-point scales measuring the eight most important domains of health status: physical functioning (PF); physical role limitations (RP); body pain (BP); general health perceptions (GH); energy/vitality (VT); social functioning (SF); emotional role limitations (RE) and mental health (MH). These domains can be aggregated into two summary measures: the Physical(PCS) and Mental(MCS) Component Summary scores.

There are studies in literature that aimed to define the factors associated with the mode of birth and the medical care provided to the patient at birth that may influence the quality of life of women (5). Also, socio-demographic, obstetric and psychosocial factors have been identified to be strongly associated with HRQoL postpartum (2, 6, 7). However, most research has been conducted in the United States and other developed countries. In addition, quality of life is a concept affected by culture and social systems. Therefore, the results of studies in other countries are not always applicable in Eastern Europe countries. Furthermore, for our knowledge, there are no studies on how prolonged perinatal hospitalization may affect postpartum HRQoL of women.

The objective of the current study was to assess the HRQoL in women from Northeast Romania and to determine the

influence of age, number of days of perinatal hospitalization and parity, on the HRQoL of women at six-weeks postpartum. The results of this study can be useful in improving the quality of life of postpartum women in Northeast Romania.

MATERIAL AND METHODS

Designing and selecting subjects for the study

This was a cross-sectional study of health-related quality of life in women who presented themselves to the gynecologist at six weeks postpartum for the indicated postnatal gynecological examination at the Cuza-Voda University Hospital in Iasi, Romania, from May to December 2021. The inclusion criteria were age over 18 years, singleton, term birth, uncomplicated pregnancy. Exclusion criteria included: a)women with severe obstetric or medical conditions, b) fetal anomalies, c) perinatal fetal death, d) a positive SARS-CoV-2 test in the last 2 months. Eligible women were informed about the purpose of the study and signed informed consent before participation. This study was approved by the local institutional ethics board (no. 74/26.04.2021, "Grigore T. Popa" University of Medicine and Pharmacy from Iasi).

Information sources

The dependent variable for this study is HRQoL, assessed through the validated SF-36 instrument, whereas the independent variables include socio-demographic characteristics such as age, and obstetrics factors such as number of days of peripartum hospitalization and parity.

Women were informed about how to complete the questionnaire in their own time.

The SF-36 questionnaire evaluates both the physical and mental components of HRQoL, and consists of 36 question, eight domains, and two component summaries. Scores for each domain range from 0 to 100, where higher scores represent better QOL. Socio-demographic and obstetric information was extracted from the medical records of the women.

Statistical analysis

The statistical analysis was performed in *SPSS 27.0.* For the qualitative data (whose values represent codes), frequency distributions were made, calculating the absolute and percentage frequencies, and the quantitative data were characterized by calculating the mean value, the standard deviation and the median value. The differences between the scales were characterized using the non-parametric Mann-Whitney test, after previously checking whether the value distributions of the scales comply with the law of normal distribution, using the Kolmogorov-Smirnov fitting test. To investigate the association between scales and quantitative variables, we calculated the Pearson linear correlation coefficient. The significance coefficient $p < 0.05$ was considered statistically significant, and $p < 0.01$ was considered statistically high significant.

RESULTS

Socio-demographic characteristics of the group

The study group consisted of 321 patients, with a mean age of 28.17 ± 6.45 years, with the youngest patient of 18 years old and the oldest of 43. Distribution of patients by age categories was relatively balanced, in the sense that 54.2% of patients were under 30 years of age and the remaining 45.8% were of 30 years of age or older; also, the group registered a slight prevalence of the rural environment

(58.9%) compared to the urban environment (41.1%).

Most patients (60.7%) gave birth naturally, and there is a significant percentage (39.3%) of patients who gave birth by Cesarean section; just over a third (38.3%) of patients have one child, the remaining 61.7% having two to six children. In general, mothers with two (29.9%) or three children (24.3%) predominate in the group. The mean number of days of hospitalization before birth was 3.81 ± 3.21, with a maximum of 14 days, and the mean number of days of hospitalization after birth was similar, with a mean of 3.84 ± 1.49 days, a minimum of 3 days and a maximum of 10 days.

Two other significant elements for the study were the exclusive breastfeeding, practiced by most patients (60.7%) and their social status – the presence / absence of a stable relationship – also the vast majority of patients (80.4%) had stated that they were in a stable relationship.

Almost a quarter of patients, 23.4%, respectively had a family history of depression. Depressive episodes were identified in 51 cases, representing 15.9% of the total number of patients; also 36 patients (11.2%) had previous hospital admissions.

Quality of life of postpartum women at 6 weeks after birth:

It can be seen from first table that the highest values are recorded for the somatic pain score, with an average of 69.25 ± 28.87 and a range of variation between 0 and 100, followed by the physical activity function of patients, calculated at a mean value of 65.42 ± 14.78, with a range of variation between 50 and 100, and the scale of social function, with an average value of 63.31 ± 29.80 and a range of variation between 0 and 100. But on the other hand, the lowest scores are observed for vitality, with an average value of 44.57 ± 20.20 and a range of variation between 0 and 95 and for the general health scale, with an average of 48.73 ± 25.99 and a range of variation between 0 and 100.

TABLE I.

Scores of postpartum women in SF-36 domains

	Mean	Standard error of mean	Standard deviation	Median	Min	Max
Physical Function (PF)	65.42	0.82	14.78	60.00	50.00	100.00
Physical Role (PR)	52.80	2.31	41.40	50.00	.00	100.00
Somatic Pain (SM)	69.25	1.61	28.87	67.50	.00	100.00
General Health (GH)	48.73	1.45	25.99	55.00	.00	100.00
Vitality (VT)	44.57	1.12	20.20	45.00	.00	95.00
Social Function (SF)	63.31	1.66	29.80	62.50	.00	100.00
Emotional Role (ER)	54.51	2.28	40.92	66.67	.00	100.00
Mental Health (MH)	57.90	1.17	21.13	56.00	.00	100.00
Physical Health (PCS)	59.05	1.08	19.48	57.50	27.50	90.00
Mental Health (MCS)	55.08	1.40	25.17	50.45	.00	97.75

The concept of Physical Health, which aggregates the first four scales, has an average value of 59.05 ± 19.48, with a range of variation between 27.50 and 90.00. In its turn, the concept of Mental Health has an average value of 55.08 ± 25.17, with a range of variation between 0 and 97.75. Therefore, both concepts investigated have

values located in the upper half of the range of possible variation, which can be appreciated as a positive fact.

Factors influencing the quality of life of postpartum women:

The age under 30 of the patients does not significantly improve their scores from a statistical viewpoint for any of the categories investigated. However, it is found that postpartum women under 30 years of age have slightly higher scores than those over 30 years of age in terms of physical function, vitality, but also somatic pain, social function, respectively; postpartum women over 30 years of age have slightly higher scores in terms of physical role and mental health. The global concepts of physical and mental health, calculated on the basis of the 8 scores, are also slightly higher in the under-30s compared to the others, but, again, the discrepancies observed are very small (tab. II).

TABLE II.

Differences in HRQoL scores according to age (Mann-Whitney U-test)

	Age < 30 years (n = 174)		Age >= 30 years (n = 147)		p-Value†
	Mean ± SD	Median	Mean ± SD	Median	
Physical Function (PF)	66.07 ± 16.12	60.00	64.64 ± 13.02	62.50	.772
Physical Role (PR)	51.72 ± 42.12	50.00	54.08 ± 40.65	50.00	.623
Somatic Pain (SM)	69.87± 27.65	67.50	68.52 ± 30.32	67.50	.845
General Health (GH)	48.96 ± 25.46	50.00	48.46 ± 26.68	55.00	.609
Vitality (VT)	45.86 ± 23.37	45.00	43.06 ± 15.59	45.00	.145
Social Function (SF)	64.22 ± 29.02	62.50	62.24 ± 30.77	62.50	.761
Emotional Role (ER)	54.59 ± 42.42	50.00	54.42 ± 39.22	66.67	.941
Mental Health (MH)	56.89 ± 24.54	52.00	59.10 ± 16.18	60.00	.635
Physical Health (PCS)	59.15 ± 18.03	54.06	58.92 ± 21.13	57.50	.557
Mental Health (MCS)	55.39 ± 27.27	46.14	54.70 ± 25.51	56.29	.550

The Pearson correlation coefficient between patients' age and SF-36 scales/ concepts also does not show significant associations; most of the values observed are very low, almost zero, with only 2 exceptions: the general health score and the mental health score, for which there are directly proportional but weak correlations with the age of the postpartum women (tab. III).

TABLE III.

Pearson correlation coefficient between SF-36 items and maternal age

	Age			Age	
	r	p		r	p
Physical Function (PF)	.006	.913	Social Function (SF)	.033	.551
Physical Role (PR)	.080	.154	Emotional Role (ER)	.068	.224
Somatic Pain (SM)	.029	.607	Mental Health (MH)	.170**	.002
General Health (GH)	.129*	.021	Physical Health (PCS)	.097	.082
Vitality (VT)	.098	.079	Mental Health (MCS)	.093	.096

Not the same can be observed in the case of parity; only the physical function has similar values in the postpartum women with one child, as compared to those with several children, for all the other scores investigated, large and highly statistically significant differences between the 2 categories of postpartum women were observed (tab. IV). Thus, postpartum women with more than one child have much higher scores, sometimes even double, than those with only one child, for all functions investigated. The largest discrepancies are found for the physical and emotional role (almost double values), and the lowest discrepancies are observed in the case of the score of vitality and that of mental health. Both the general concept of physical health and that of mental health are also significantly increased, by approx. 25%, for postpartum women with several children compared to those with only one child.

The number of days of hospitalization before birth is inversely correlated with all the scales investigated, and statistically significant in all cases with one exception (general health scale) – which means that as the number of days of hospitalization before birth increases, the values of the scales investigated decrease. The highest correlation coefficients are found with the scale of vitality and that of mental health, but also with the global concept of mental health, and the lowest correlations are observed with the scales of somatic pain and social function, but also with the global concept. physical health (tab. V).

DISCUSSION

Assessment of quality of life of women in postpartum period is essential for global healthcare, however only a few studies have monitored these women's HRQoL. Most studies focused on how a particular pre-existing or pregnancy-associated pathology affects a woman's quality of life during pregnancy. Studies suggest that HRQoL in pregnant women depends on socioeconomic, medical, and psychological factors(2,6,7). Low HRQoL during pregnancy is associated with an increased risk of preterm birth and restricted intrauterine growth. Among the articles on quality of life during pregnancy with associated pathologies), we observe a wide range of studied pathologies, such as depression (8), urinary tract disorders (9), diabetes (10), hypertension (11) and obesity (12). There is, however, a predominance of quality-of-life articles in pregnant women in relation to depression, representing an interest that is twice as high as for any other pathologies associated with pregnancy (6, 13, 14).

Maternal and child health professionals focus on prenatal care, while the postpartum period remains neglected, although research has been conducted in recent decades to study various aspects of postnatal care and its related QoL(15). It is therefore not surprising that the care given to the postpartum women has been criticized by them, being inadequate in meeting the needs of these women. For example, in the UK, the postpartum follow-up of the patient six weeks after birth involves gynecological examination and discussion about family planning, neglecting the patient's mental health(3). In Romania, the recommendations for the woman who has just given birth are to come as soon as possible after discharge to the medical dispensary in the territory of her home for both the patient and the newborn to be registered, and to perform a gynecological exam in six weeks postpartum. Unfortunately, due to financial problems or long distance from the maternity ward, just a few patients return to a gynecological exam.

Numerous postpartum morbidities have been reported to influence HRQoL. Asthenia or fatigue is the most common postpartum physical health problem, found in over 50% of women (16). Fatigue is associated with postpartum depression and breastfeeding problems. Another common symptom among women in postpartum period is pain located in different areas of the body. Urinary incontinence, hemorrhoids, constipation, sleep disturbances and a variety of emotional changes, such as depressive symptoms, are examples of other conditions that affect the physical and mental health of new mothers. These health problems affect not only the health of the baby, but also the wellbeing of the newborn. Therefore, inadequate postpartum supervision of the women affects the quality of life of both mothers and newborns.

Women who have just given birth face many changes with repercussions on their physical and mental status. Statistics show that in the first two months after birth, 86% of these women have physical problems and 10-12% suffer from postpartum depression (17).

The results of our study reported the mean PCS and MCS scores both higher than 50% (59.05 ± 19.48, 55.08 ± 25.17, respectively). The results are comparable with a study conducted in Kuwait, with the mean PCS and MCS scores 54.5 and 52.9 respectively but are lower than studies conducted in Spain where overall HRQoL mean score at less than one year since last

birth is 71.94 ± 17.48 (5,18). Also, the results of a study conducted in Ethiopia on 409 randomly selected post-partum women showed that the PCS Mean±SD score was higher in Mean±SD score (49.5±9.3) when compared with the MCS Mean±SD score of 40.79±10.90, but both scores were lower than our study results(19). The socioeconomic discrepancy of the study participants may be the reason for the difference between the results of these studies. A higher quality of life is favored by a higher socioeconomic standing. A further variation could be brought on by the differences in the study population. In this study we included women at six weeks postpartum, whereas the study conducted in Spain included women who gave birth in the year before and the Ethiopian study and the one conducted in Kuwait included women who gave birth in the last 6 months.

Postpartum women from Northeast Romania scored higher in physical functioning, bodily pain and social functioning. The lowest scores were observed in the vitality and general health perceptions dimensions. Our findings are similar to Spanish study results, where the score of vitality dimension was the lowest of the scores of the eight dimensions and the score of physical functioning was the higher of the scores.

There are studies that have tried to define the factors associated with the birth and health care of peripartum women, which may influence the quality of life of these women in postpartum period. Therefore, one of the factors that affects the quality of life after childbirth is the delivery method(5). According to the results of the Spanish study, Cesarean section is a factor that negatively influences postpartum QoL.

Based on findings from similar research that were considered as particular predictors of HRQoL in postpartum women, we used several simple predictors as the input variables. Thus, maternal age was shown to have an association with HRQoL; the mean PCS and MCS scores are higher in women under 30 years of age. However, the results are contrary to the Ethiopian study according to which women who were in the age group 17-24 were more likely to have lower level HRQoL. This may be due to the tendency for women to become pregnant later in their reproductive life (20). Also, in the current finding maternal age was directly proportional to general health perceptions and mental health.

Another putative factor studied in this research was parity. Our results showed that multiparity positively influences scores. The more children the woman has, the higher the scores. In our study, the PCS and MCS scores were at least 25% higher in multiparous women. Other studies found that multiparity was negatively related to mental health (21, 22).

Number of days of peripartum hospitalization is another factor that showed a statistical association with postpartum HRQoL so such the longer the duration of peripartum hospitalization, the more negatively affected the postpartum HRQoL. In our study the number of days of hospitalization was inversely proportional to all scales of the SF-36 questionnaire. The most affected domains were vitality and mental health. The minimum length of peripartum hospitalization is controversial. In the USA and Western countries, the pregnant woman is hospitalized when the labour is onset, when the patient has regular painful uterine contractions associated with progressive changes of the cervix and dilation. But on the other hand, considering the fact that many of the

pregnant women in Romania come from rural areas, from localities far from a maternity hospital, where they cannot benefit from specialized medical help in case the birth is imminent, the decision not to hospitalize a patient with irregular uterine contractions involves many risks assumed by the obstetrician. He cannot predict how the patient's contractions will progress, as well as the moment of labour onset. Thus, many of the patients with a diagnosis of prelabour, "false labour" or latent phase of labour, remain hospitalized for long periods, until birth, increasing the costs of maternity, and the risk of their quality of life being affected in postpartum period.

Also, in the USA, the mother and her newborn are discharged at 24-48 hours postpartum, regardless of the mode of birth (vaginal delivery or C-section), while in Romanian maternities, protocols suggest discharging them at minimum 72 hours from birth. The hospitalization is extended until the medical team that attended the birth considers the mother and the newborn out of any danger of medical complication. Thus, peripartum, women in Romania spend more time hospitalized compared to women in other countries, and the implications on the quality of life of these women cannot be overlooked. Again, we emphasize that the results of studies on the quality of life of women from other countries in postpartum period, do not define the quality of life of Romanian women in postpartum period.

The existing literature demonstrates the association between prolonged hospitalization and a low quality of life after discharge in various categories of patients. For example, studies showed that women with a high-risk pregnancy who are hospitalized for a long-time during pregnancy have a higher risk of impaired mental and physical health compared to pregnant women hospitalized peripartum for the minimum period of time required for childbirth and recovery (23). Indeed, the fact that the patient's pregnancy is classified as a high-risk pregnancy may affect the woman's mental health (24). HRQoL after discharge was also investigated in elderly patients who required prolonged hospitalization. Among them, a low quality of life was found as compared to people of the same age who did not need hospitalization(25). Of course, these categories of patients have been hospitalized for a long period of time (weeks or even months), while after birth, women in Romania spend an average of 3 days in hospital. However, every day away from the family, in a new, unknown environment, affects the quality of life of these women.

CONCLUSIONS

This study identified maternal age under 30 and multiparity to be associated with higher postpartum HRQoL of women from Northeast Romania. Also, the longer the peripartum hospitalization period, the lower the mental and physical health at six weeks postpartum.

In this regard, we highlight the need for additional studies on ways to predict the onset of labour, in order to delay the admission of term pregnant women and shorten the hospitalization period of those hospitalized (26). Implicitly, the use of biomarkers with a predictive role in determining the moment of the onset of labour would have as repercussions the increase of the quality of life of Romanian women in postpartum period.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

NEWS

GUT MUCOSA MICROBIOTA IN ULCERATIVE COLITIS: RELAPSE AND TREATMENT RESPONSE IN ADULTS

A longitudinal study in UC investigates whether the mucosal gut microbiota is associated with relapse events and treatment response, by means of RNA-based 16S rRNA analysis which detects not only live and active microbes but also dead and dormant microbes. 51 adult patients (age>20) were included in this study with mean age of 45, between 2012 and 2017 and followed up through 2020; patients who had taken antibiotics within 3 months before biopsies and with primary sclerosis cholangitis were not enrolled in this study; no patients enrolled developed colorectal cancer during the follow-up period. Colon mucosal biopsy were obtained at enrollment and 16S rRNA sequencing was performed. 24 patients were in remission of which 7 developed relapses during follow-up and 27 in active UC which were classified into response group (n=6), refractory group (n=13) and non-response group (n=8) according to their treatment response in 6 months. Results**:** no difference in the gut microbiota composition between rectum and colon; the proportion of Bacteroides decreased as the severity of mucosal inflammation increased; unexpectedly Bacteroides was significantly lower in the non-relapse group than in the relapse group; secondly, the proportion of Enterobacteriaceae increased as the mucosal inflammation increased; in the active period a high proportion of Enterobacteriaceae was resistance to any treatments; the proportion of Clostridiales was higher in the non-relapse group whereas Prevotella was higher in the response group. In conclusion, gut microbiota composition can predict treatments strategies and clinical course of UC in terms of the relapse rate during the remission period and intractability during the active phase. (Nishihara Y, Ogino H, Tanaka M, *et al.* Mucosa-associated gut microbiota reflects clinical course of ulcerative colitis. *Sci Rep* 2021; 11: 13743 / https://doi.org/10.1038/s41598-021-92870-0).

VIRAL B AND C HEPATITIS IN RHEUMATIC PATIENTS UNDER BIOLOGICAL THERAPY

VIRAL B AND C HEPATITIS IN RHEUMATIC PATIENTS UNDER BIOLOGICAL THERAPY (Abstract): Both rheumatic immune-inflammatory diseases and viral hepatitis represent important health problems worldwide. Modern therapies with biological and targeted synthetic disease-modifying antirheumatic drugs (b/tsDMARDs) have revolutionized the management of immune-inflammatory diseases. However, these therapies have a strong immunosuppressive impact, patients being at risk of reactivation of viral hepatitis. The aim of this study was to assess the prevalence and the risk of reactivation of B and C hepatitis (HBV, HCV) in rheumatic patients who are treated with b/tsDMARDs for rheumatoid arthritis (RA) and ankylosing spondylitis (AS). **Material and methods:** We retrospectively analyzed all patients with RA and AS receiving b/tsDMARDs therapies in the Rheumatology department over a one-year period. Serological screening for HBV infection (HBsAg, anti-HBc, anti-HBs) and HCV antibodies was performed in all patients. For each patient we reviewed the diagnosis, demographic data, type of the treatment, HBV and HCV serology, viral infection treatment. **Results:** There were 132 patients diagnosed with RA and 90 patients diagnosed with AS receiving therapy with bDMARDs or tsDMARDs. 65 of the patients with RA (49.24%) and 32 of those with AS (35.55%) presented changes in viral markers. Both in the group of patients with RA and those with AS, approximately 10% of patients showed previous B vaccination. Only 2.27% of the patients with RA and 1.11% of those with AS presented chronic B infection. Most of the patients (36.36% RA, 24.44% AS) had resolved B infection. Inactive HCV infection was found in 2.25% of total number of patients. A percentage of 12.12% among those with RA and 3.33% of those with AS received treatment with Entecavir/Tenofovir. There were no cases of hepatitis reactivation. **Conclusions:** Viral B infection has a high prevalence in patients with RA and AS. Screening for chronic viral B and C infections should be done in all patients with autoimmune rheumatic diseases. Treatment with nucleotide/nucleoside analogs is effective in preventing HBV flare regardless of the type of b/tsDMARDs. All patients with viral C infection should be treated with direct-acting antivirals. **Keywords:** VIRAL HEPATITIS, RHEUMATOID ARTHRITIS, ANKYLOSING SPONDILITIS, BIOLOGICAL THERAPY.

Both rheumatic immune-inflammatory diseases and viral hepatitis represent important health problems worldwide. Chronic hepatitis B (HBV) and C virus (HCV) infection are major causes of morbidity and mortality, leading to cirrhosis, hepatocellular carcinoma, and liver transplantation (1). The prevalence of hepatitis varies between populations, and even in areas with low endemic levels it is necessary to identify those whose current or previous infection could influence their clinical outcome (2). It is estimated that approximately 1 in 3 individuals in this world may have been exposed to HBV infection (3,4), and 110 million persons are HCV antibody-positive, with 80 million viremic HCV infection (5).

The treatment of patients with rheumatoid arthritis (RA) and ankylosing spondylitis (AS) is aimed at relieving symptoms, improving physical function and quality of life, and preventing structural damage (6). Pharmacological options include (6,7):

- conventional synthetic (cs) disease-modifying antirheumatic drugs (DMARDs) such as Methotrexate, Leflunomide, Sulfasalazine;
- biological (b) DMARDs, including tumor necrosis factor (TNF) inhibitors (Adalimumab, Etanercept, Infliximab, Certolizumab, Golimumab), T-cell stimulation modulators (Abatacept), interleukin-6 (IL-6) receptor antagonists (Tocilizumab), interleukin-1 (IL-1) inhibitors (Anakinra) , interleukin-17 (IL-17) inhibitors (Secukinumab) and anti-CD20 antibodies (Rituximab);
- targeted synthetic (ts) DMARDs, such as Janus kinase (JAK) inhibitors (Tofacitinib, Baricitinib and Upadacitinib).

The new therapies (b/ts DMARDs) have revolutionized the management of rheumatic immunoinflammatory diseases. However, these therapies have a strong immunosuppressive impact. Patients receiving this treatment have the risk of reactivation of viral hepatitis - especially reactivation of HBV infection (HBVr) (8, 9). Recent guidelines advice to perform a complete hepatitis status screening before starting biologic therapy (2, 8, 10). This involves testing for four serological components of hepatitis infection: hepatitis B surface antigen (HBsAg), hepatitis B surface antibody (anti-HBs), hepatitis B core antibody (anti-HBc) and hepatitis C antibody (HCV) (2). HBsAg indicates the presence of acute or chronic hepatitis B infection, anti-HBc antibodies may be present in acute, chronic or resolved infection, anti-HBs antibody may indicate resolved infection, or vaccination if found alone (2,11). Before the initiation of biological therapy, antiviral therapy is recommended for positive HbsAg patients, while for negative HbsAg, positive anti-HBc patients recommendations of the guidelines are not uniform, varying between monitoring and treatment. Anti-HBV drugs with a high resistance barrier, such as entecavir or tenofovir, should be preferred over low-barrier agents such as lamivudine (12).

Although all rheumatologists should be aware that the immunosuppression associated with b/tsDMARDs can provoke HBVr, with a significant morbidity and mortality of susceptible patients, screening and treatment practices for B and C viral infections are extremely varied worldwide (13). In addition, the risk of reactivation of viral infections under new b/tsDMARDs other than anti-TNF agents is incompletely known.

The aim of this study was to assess the prevalence and the risk of reactivation of B and C hepatitis in rheumatic patients who are treated with b/tsDMARDs for RA and AS.

MATERIAL AND METHODS

Study design and patients

We retrospectively analyzed all patients with RA and AS receiving b/tsDMARDs therapies in the Rheumatology department (a tertiary referral care center), over a one-year period, between 1st September 2021 and 1st September 2022. Data among these patients were screened from the first b/tsDMARDs administration to the last visit to our hospital. Data were collected from the Romanian Registry of Rheumatic Diseases. This study was performed in accordance with the ethical principles of the Declaration of Helsinki. All patients have signed inform consent before therapy initiation.

Diagnosis of RA and AS

Diagnosis of chronic rheumatic diseases was established according to criteria recommended by international guidelines. The diagnosis of RA was based on the 1987 American College of Rheumatology criteria (14) or 2010 American College of Rheumatology/European League Against Rheumatism collaborative initiative (ACR/EULAR) classification criteria (15). The diagnosis of AS was established according to the modified New York 1984 criteria (16).

Diagnosis of HBV and HCV infections

Serological screening for HBV infection (HBsAg, anti-HBc, anti-HBs) and HCV antibodies was performed in all patients. Based on the results of the screening tests, patients were categorized to the following groups:

1. Non-modified serological markers (HBsAg-, anti-HBc-, anti-HBs-, anti-HCV);
2. Previous B vaccination (HBsAg-, anti-HBc-, anti-HBs+);
3. Chronic B infection (HBsAg+, anti-HBc+, anti-HBs-);
4. Resolved HBV infection (HBsAg-, anti-HBc+, anti-HBs±);
5. HCV infection (anti-HCV+).

According to the Romanian protocol for the treatment of viral B infection in patients under immunosuppressive treatment (17), all patients with positive HBsAg, as well as those with negative HBsAg, positive anti-HBc and anti-HBs <10 mIU/mL received prophylactic treatment with nucleoside/nucleotide analogues (Entecavir/ Tenofovir).

Data collection. For each patient we reviewed the diagnosis, demographic data, type of the treatment, HBV and HCV serology, viral infection treatment.

RESULTS

Baseline characteristics of the patients

There were 132 patients diagnosed with RA and 90 patients diagnosed with AS receiving therapy with bDMARDs or tsDMARDs. In the group of patients with RA, the majority were female, and the average age was 62.68 years. In the group of patients with AS, the majority were male, the average age being lower than in the group of patients with RA. We note that patients with AS mostly received anti-TNFα treatment (according to the Romanian treatment protocol), only 4.44% being treated with anti-IL-17. In the group of patients with RA, the majority received anti-IL-6 treatment, followed by those with anti-TNFα, but also with JAK-kinase inhibitors in a close percentage (tab. I).

TABLE I.
Baseline characteristics of the study group

Parameter	RA (n=132)	AS (n=90)	Total (n=222)
Sex M	34 (25.75%)	66 (73.33%)	100 (45.04%)
F	98 (74.24%)	24 (26.66%)	122 (54.95%)
Medium age	62.68±9.42	51.15±14.31	58.84±12.53
Treatment			
Anti-TNF	41 (31.06%)	86 (95.55%)	127 (57.20%)
Infliximab	4 (3.03%)	9 (10%)	13 (5.85%)
Adalimumab	15 (11.36%)	33 (36.66%)	48 (21.62%)
Etanercept	16 (12.12%)	28 (31.11%)	44 (19.81%)
Certolizumab	2 (1.51%)	5 (5.55%)	7 (3.15%)
Golimumab	4 (3.03%)	11 (12.22%)	15 (6.75%)
Anti-interleukins	47 (35.60%)	4 (4.44%)	51 (22.97%)
Tocilizumab	47 (35.60%)	-	47 (21.17%)
Secukinumab	-	4 (4.44%)	4 (1.80%)
JAK inhibitors	38(28.78%)		38 (17.11%)
Tofacitinib	17 (12.87%)	-	17 (7.65%)
Baricitinib	16 (12.12%)	-	16 (7.20%)
Upadacitinib	5 (3.78%)	-	5 (2.25%)
Anti-B-cell agents			
Rituximab	6 (4.54%)	-	6 (2.70%)

The presence of markers of B and C viral infections

65 of the patients with RA (49.24%) and 32 of those with AS (35.55%) presented changes in viral markers. Both in the group of patients with RA and those with AS, more than half did not show any change in viral markers. Regarding vaccination, both in the group of patients with RA and those with AS, approximately 10% of patients (13 of those with RA and 9 of those with AS) showed positive anti-HBs antibodies, these being considered subjects immunized by vaccination.

Most of those who presented changes in the serological markers were those with resolved HBV infection (48 patients with RA and 22 patients with AS). Among them, in the case of patients with RA, 35 subjects (26.51% of total number of patients) presented anti-HBc+ and anti-HBs+, meaning spontaneous seroconversion. They did not require prophylactic treatment. 13 patients (9.84% of total number of patients) presented only anti-HBc+, without protective titer of anti-HBs antibodies. All these patients received treatment with Entecavir/ Tenofovir. In the case of patients with AS, approximately 20% of total number of subjects presented spontaneous seroconversion, with protective titer of anti-HBs. Two patients showed anti-HBc+, anti-HBs- and they also received treatment with Entecavir.

Only two of the patients with RA and one patient with AS presented HBsAg+, anti-HBc+, anti-HBs-, these being classified as patients with chronic B infection. These patients also received antiviral treatment with NAs resulting a total of 16 patients among those with RA (12.12%) and 3 (3.33%) of those with AS being treated with Entecavir / Tenofovir.

Among the patients with RA, 4 subjects

showed positive anti-HCV, 2 of them associated with resolved HBV infection, one with chronic B infection, and one with no changes in serology for hepatitis B. Also, one patient with AS associated inactive HBV + HCV infection. All five patients had sustained virologic response to HCV treatment (tab. II).

TABLE II.

The presence of markers of B and C viral infections

Type of viral infection	RA	AS	Total
Non-modified serological markers (HBsAg-, anti-HBc-, anti-HBs-, anti-HCV-)	67 (50.75%)	58 (64.44%)	125 (56.30%)
Previous B vaccination (HBsAg-, anti-HBc-, anti-HBs+)	13 (9.84%)	9 (10%)	22(9.90%)
Chronic B infection (HBsAg+, anti-HBc+, anti-HBs-)	3 (2.27%)	1(1.11%)	4 (1.80%)
Resolved HBV infection (HBsAg-, anti-HBc+, anti-HBs±)	48 (36.36%)	22 (24.44%)	70 (31.53%)
HCV infection (anti-HCV+)	4 (3.03%)	1 (1.11%)	5 (2.25%)

Viral infection reactivation

Among the patients with chronic B infection, half were treated with anti-TNFα and half with JAK-inhibitors. Most of the patients with resolved HBV infection were treated with anti-TNFα (47.14%), followed by anti-IL-6 treatment (34.28%) and JAK-inhibitors treatment (12.85%). Among the patients with HCV infection, 80% were under anti-TNFα treatment and one patient under JAK-inhibitors treatment (tab. III).

There was no case of hepatitis reactivation during the follow-up period.

TABLE III.

Relationship between the type of treatment followed and the B and C infection markers.

Type of treatment	Chronic B infection	Resolved HBV infection	HCV infection
Anti-TNFα	2 (50%)	33 (47.14%)	4 (80%)
Anti-IL-6	0 (0%)	24 (34.28%)	0 (0%)
Anti IL-17	0 (0%)	1 (1.42%)	0 (0%)
JAK-inhibitors	2 (50%)	9 (12.85%)	1 (20%)
Anti-CD20 antibodies	0 (0%)	3 (4.28%)	0 (0%)

DISCUSSION

Chronic viral hepatitis B and C represent a real public health problem. Despite the fact that they can be asymptomatic for many years, they have the potential to progress to liver cirrhosis, hepatocarcinoma and death. In immune rheumatic diseases, such as RA and AS, there is an increased risk of activation of viral infections as a result of immunosuppressive treatment.

It is considered that HBV and HCV infection have the same prevalence in rheumatic diseases patients as in the general population. In these patients the prevalence of positive HBsAg is estimated at 3-3.5%, past HBV infection between 13-50% and anti-HCV positive 1.2% (18,19). The prevalence data from our study (HBsAg was found in 1.80% of the patients, past HBV infection in 31.53% and anti-HCV positive in 2.25% of the patients) are similar to the data from the literature. In our study, we recorded a higher prevalence of HBV infection markers in patients with RA com-

pared to those with AS, a fact also reported in other studies in the literature (20). Most patients had the profile of negative HBsAg/positive anti-HBc/positive anti-HBs; only 4 patients had positive HBsAg. It should be mentioned that in Romania the complete screening of HBV infection (HBsAg, anti-HBc, anti-HBs) is mandatory for all patients who initiate b/tsDMARDs. In the USA, for example, only 1/3 of the patients of the national Rheumatology Informatics System for Effectiveness (RISE) registry have the full screening done (21). In Mohareb's study (22), only 29% of the patients who initiated tocilizumab and 24% of those who initiated tofacitinib had complete screening for HBV infection.

There is evidence regarding the risk of reactivation of viral B infection under biological therapy (23,24). The reactivation rate of HBV infection in patients with rheumatological diseases seems to be lower compared to data from oncology or hematology: only 1.4% in the meta-analysis performed by Moghoofei (25). However, in patients with B viral infection treated with anti-TNF agents, who did not receive prophylactic antiviral therapy, reactivation of HBV infection occurred in up to 75% of patients (19). The risk of reactivation of HBV infection is much lower in HBsAg negative/anti-HBc positive patients: 1.7% in Lee meta-analysis (26).

In Romania, the protocol of the National Health Insurance House (17) stipulates that all patients who initiate immunosuppressive therapy or chemotherapy should be screened for markers of HBV infection. All HBsAg - positive or anti-HBc positive subjects (without positive anti-HBs) will initiate therapy with nucleotide/nucleoside analogues during immunosuppressive therapy and 6 months after stopping it. Patients with negative HBsAg, positive anti-HBc and positive anti-HBs (> 10 mIU/mL) will be closely monitored at 3 months. Following the national protocol, all HBsAg positive or anti-HBc positive patients (without anti-HBs positive antibodies) benefited from prophylactic antiviral treatment with Entecavir or Tenofovir before starting b/tsDMARDs. During the studied period, we did not register a single case of reactivation of the B viral infection. Many authors have shown that the prophylactic treatment with analogues is effective for preventing HBV flare both in HBsAg positive and in anti-HBc positive patients (23). The lack of reactivation of viral B infection in our study is explained by the prophylactic treatment of all patients with HBV markers, including those with negative HBsAg, which is different from most other countries. Current practice in most countries involves - in the case of patients with resolved HBV infection - only monitoring without initiation of antiviral treatment (27).

Data from the literature regarding the risk of reactivation of HBV infection under the new biological and targeted synthetic therapies are poor, given that HBV positive patients were excluded from the pivotal studies. Rituximab, an anti-CD20 agent, is known from oncology-hematology for the increased risk of reactivation of viral B infection. In rheumatic diseases this risk seems to be lower (2%) (19). The data on Abatacept, interleukin inhibitors and oral targeted therapies (JAK inhibitors) regarding the risk of HBV reactivation come from small, retrospective studies or case reports. Lin's meta-analysis (28) showed the same risk of reactivation of HBV infection regardless of the type of b/tsDMARDs used: anti-TNF, other biological, non-biological therapies. It is generally accepted that the risk and management of patients is similar in the new b/tsDMARDs therapies to that of anti-

TNF agents. A significant proportion of patients included in our study were treated with non-anti-TNF biological agents and JAK inhibitors. Our study showed that prophylaxis with nucleoside/nucleotide agents is also effective in the case of these new therapies in RA and AS.

According to the Romanian protocol, patients with anti-HBs over 10 mIU/mL did not initiate prophylactic treatment with nucleotide/nucleoside analogs. Indeed, data from the literature reveal a low risk of HBV reactivation in patients with positive anti-HBs, directly proportional to their titer (29,30). However, Tien's study (31) demonstrated that there is still a low risk of HBV reactivation in patients with low anti-HBs titers (<100 mIU/mL), which explains the monitoring of these patients. The loss of anti-HBs in patients with rheumatic diseases under treatment with b/tsDMARDs is greater in patients who associate chronic kidney disease (32).

We note a small percentage of patients vaccinated against B virus (9.90%). This revealed deficiencies in the management of these patients. An explanation can be the increased average age of the studied group, taking into account that in Romania mandatory B vaccination at birth only started in 1996. In Romania, a country with a high prevalence of viral hepatitis B, ideally all patients with RA and AS should be screened for markers of HBV infection, right from diagnosis. If they are negative, the complete vaccination schedule is indicated.

Regarding the C virus, there are no special recommendations related to immunosuppressive therapy, the risk of reactivation of the viral infection being reduced. In Patel's study (33), RA and HCV patients had higher rheumatic disease activity scores and were more likely to be treated with cortisone or biologics. Considering the hepatotoxicity potential of b/tsDMARDs, treatment with direct-acting antivirals is ideally recommended before starting immuno-suppressive treatment. Some recent data in the literature suggest improvement in RA activity scores after achieving a sustained viral response in patients with C virus treated with direct-acting antivirals (34). Italian group for the Study and Management of the Infections in patients with Rheumatic diseases (36) recommends screening for HCV infection and treatment with direct-acting antivirals for all patients, ideally before starting treatment with DMARDs. Anti-TNF agents can be administered concurrently with DAA therapy. In the case of patients in whom viral eradication cannot be done, DMARD therapy is not contraindicated, but liver function must be carefully monitored. In our studied group there were only 5 cases of viral C infection, all 5 having sustained viral response after oral antiviral treatment.

The limitations of our study are the short follow-up period (one year), the retrospective nature and the lack of evaluation of all parameters related to the viral infection (viremia level, hepatic fibrosis staging). However, it is a study conducted in a tertiary rheumatology center, which included a large number of patients, brought new epidemiological data (unknown in Romania), and analyzed patients with various biological and JAK inhibitors.

CONCLUSIONS

Viral B infection has a high prevalence in patients with RA and AS, most patients being negative HBsAg, positive anti-HBc, positive anti-HBs. Screening for chronic viral B and C infections should be done in all patients with autoimmune rheumatic diseases, right from the moment of diagnosis. Treatment with nucleotide / nucleoside

analogs is effective in preventing HBV flare regardless of the type of b/tsDMARDs. All patients with viral C infection should be treated with direct-acting antivirals. Additional efforts are needed so that all patients with autoimmune rheumatic diseases, likely to receive immunosuppressive treatment throughout their lives, should be vaccinated against the B virus.

FIRST-LINE MEROPENEM ANTIBIOTIC THERAPY IN ACUTE PERITONITIS SECONDARY TO COLIC PERFORATION. CLINICAL AND HISTOPATHOLOGICAL STUDY ON THE LABORATORY ANIMAL (Abstract): Acute peritonitis accounts for 1% of all on-call visits and is the second leading cause of sepsis worldwide. Annually, due to secondary peritonitis, it is estimated that 20 million years of life are lost, 25 million years are adjusted for disabilities and 896,000 deaths. Fecal peritonitis is one of the most common causes of intensive care admissions with a mortality rate between 19.1 and 31.6% in some centers exceeding 50%. **Material and methods:** Taking into account the above, we imagined a study, using laboratory animals, in which we produced sigmoid perforations, then followed their evolution without antibiotic treatment and under antibiotic therapy with Cefuroxime 25 mg/kg/24 hours intravenously or Meropenem 40 mg/kg intravenously, following the tissue changes both macroscopically and microscopically. **Results:** Our study revealed a mortality rate of 3.33%, the death occurring within 72 hours from the time of perforation. By observing the general condition (clinical point of view), no major differences between batches were found, neither from a macroscopic point of view (inspection of the peritoneal cavity). After microscopic analysis of the peritoneum and sigmoid colon meropenem treatment showed remarkably better results, especially at T4. **Conclusions:** Meropenem is a first-line antibiotic in acute peritonitis secondary to colonic perforation, which together with surgery can reduce the morbidity and mortality of this pathology. **Keywords:** PERITONITIS, DIGESTIVE PERFORATION, MEROPENEM, CEFUROXIME, MICROSCOPY.

Acute peritonitis accounts for 1% of all on-call visits and is the second leading cause of sepsis worldwide (1). Annually, due to secondary peritonitis, it is estimated that 20 million years of life are lost, 25 million years are adjusted for disabilities and 896,000 deaths (2).

Fecal peritonitis is one of the most common causes of intensive care admission for with a mortality rate between 19.1 and 31.6% (3) in some centers exceeding 50% (4), the average time of hospitalization in intensive care being about 5 - 12 days (5, 6). The most important predictors of mortality in fecal peritonitis are acute renal failure, acute heart dysfunction, elevated APACHE II scores, hypothermia, advanced age, and elevated lactate levels (3, 5, 7). The main causes of fecal peritonitis are colonic perforations (8), especially perforated diverticulitis and anastomosis dehiscence (3), with surgical treatment in the foreground, respecting three goals: removal of the septic source, excision of necrotic tissue and drainage of purulent collections (9), accompanied by appropriate intensive care measures and good pre- and postoperative antibiotic therapy. Good detection of the microbial factor involved, and the administration of effective antibiotic therapy can reduce the average number of days of hospitalization in intensive care from 12 to 6.6 days (6), thus reducing the costs by over 65,000,000 USD (6).

At present, inadequate antibiotic therapy is administered in approximately 20% of cases of septic shock, leading to increased mortality and morbidity (10).

In view of the above, we imagined a study using laboratory animals, in which we produced perforations of the sigmoid colon, then we followed their evolution without antibiotic treatment and under antibiotic therapy with Cefuroxime 25 mg/kg/24 hrs. intravenously (11) or Meropenem 40 mg/kg intravenously (12), following at certain times the tissue changes of the affected organ and of the peritoneum both macroscopically and microscopically.

MATERIAL AND METHODS

The study was done at the National Research Institute for Medical-Military Development "Cantacuzino", Băneasa Department (Romania), Preclinical Testing Unit, according to the rules of the Organization for Economic Cooperation and Development (OECD) in good laboratory practice(GLP), the Romanian laws and the internal protocols, with the authorization of the Veterinary Authority and the Ethics Committee of the "Cantacuzino" Institute. We used the Wistar strain rats, aged between 14-16 weeks and with body weights between 150-300 g at the beginning of the study. We used 35 animals, both female and male, healthy young adults, who had not been involved in previous tests. The rats were bred by the Băneasa Animal Breeding Department of the "Cantacuzino" Institute, and the identification of the laboratory animals was done individually. The acclimatization of the animals lasted eight days and was carried out under the same conditions as the study. The animals were housed in individual cages, identified by a label indicating the species, strain, age, sex, identity of the animals, group, cage number, project acronym, and experimental procedure, according to the protocols. The cages were made of polycarbonate and complied with the surface area established by the rules in force. The animals were kept at a temperature of 18-24°C, with a relative humidity of 30-70%, ensuring a light and dark cycle of 12 hours. The animals were fed standard granulated food and drinking water, ad libitum. The

feed and water did not contain any known contaminants to interfere with the results of the experiment. The test lab and pet rooms were also restricted areas.

The animals were divided into four groups (A, B, C, D). Group A, consisting of 5 rats, represented the control group, and the 10 rats in each group - B, C and D were perforated in the sigmoid colon, which was defined as T0. General anesthesia of the animals was performed with a mixture of Ketamine (0.35 mg/kg body weight) + Aceprosamine (0.3 mg/kg body weight) + O2 with Isoflurane. Postoperatively, the animals in groups B, C and D received treatment with Ketoprofen, and antibiotic therapy was administered as follows: group B did not receive antibiotic treatment, group C received antibiotic treatment with Cefuroxime, and group D received treatment with Meropenem.

Four points of time were defined: T0 - the time when the sigmoid perforation was produced (all subjects from the group A were sacrificed), T1 - 24 hours postoperatively, T2 - 48 hours postoperatively, when some of the subjects (5 from each group B, C, D) were sacrificed and histopathological samples were collected, T3 - 72 hours postoperatively and T4 - 96 hours postoperatively, at which time the subjects were sacrificed and histopathological samples were collected.

At time T0, in the case of all subjects in group A, a median incision was made through which it entered the peritoneal cavity, and then a sigmoid colon resection was performed (fig. 1a) and a sample from the parietal peritoneum. The samples were processed and stained with Hematoxylin-Eosin (HE), then analyzed using an optical microscope (OM). After resection of the sigmoid colon and the sample from the parietal peritoneum, subjects in group A were euthanized, according to internal euthanasia procedures, with an overdose of anesthetics. In the case of groups B, C and D, a median incision was made in the upper half of the abdomen through which it entered the peritoneal cavity, and intraperitoneally an incision was made in the sigmoid colon, about 0.5 cm (fig. 1b).

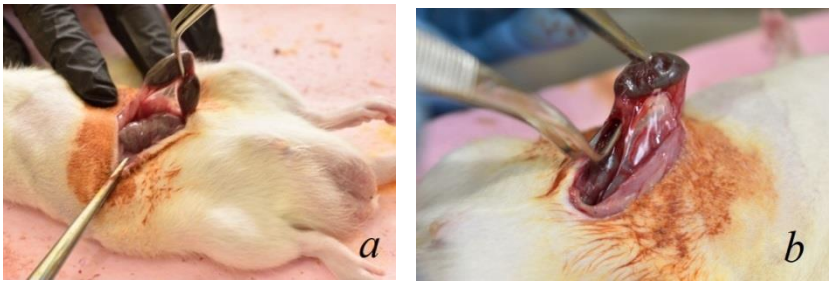

Fig. 1. a) Penetration into the peritoneal cavity and isolation of the sigmoid colon; b) Colon perforation at time T0

The sigmoid was carefully handled to prevent further intraperitoneal damage. After making the incision at the level of the sigmoid, a parietoraphy was performed in 2 planes (suturing the musculo-aponeurotic layers and suturing the skin) with a suture type with polypropylene 0 thread. The postoperative wound was cleaned, and the subjects were placed in their cages. Please note that no problems were encountered during the proceedings. Following the procedures from time T0 in all 3 groups, B, C

and D, each subject was monitored until returning from anesthesia. In the following days, each live animal received anti-inflammatory treatment (Ketoprofen 3 mg/ kg body weight, administered intramuscularly), the antibiotic treatment is administered as follows: in the case of subjects in group B no antibiotic was administered, in the case of subjects in group C it was administered Cefuroxime 25 mg / kg / 24 hrs. intravenously, and Meropenem 40 mg/kg intravenously was administered to subjects in group D. Throughout the study, the animals received food and water at their discretion.

At time T2, we intended to randomly select five subjects from groups B, C and D, which entered the peritoneal cavity by removing the sutures from the parietoraphy, in order to observe local macroscopic pathological changes, and after resection sigmoid colon and a sample from the parietal peritoneum, The samples were to be subjected to a histopathological examination to detect microscopic pathological changes.

At time T4, we intended that the remaining five subjects in each group (B, C, D) be subjected to procedures similar to those in T2, in order to observe the evolution of acute peritonitis in dynamics.

RESULTS

At time T0 we microscopically analyzed the sigmoid (fig. 2) and peritoneum resected from subjects in group A (control group), in which no perforation was produced in the digestive tract. No macroscopic and microscopic pathological changes were found.

From a clinical point of view, the subjects from all 3 groups showed favorable evolutions, being registered only one death at the level of group D at the time of T3. Subjects in all 3 groups showed good general condition and weight gain, except for subjects in group B who at time T2 showed a slight decrease in average weight. Thus, in the case of group B at time T0, the average weight was 219.52 grams, at time T2 218.84 grams, and at time T4 237.48 grams. In the case of group C at the time of T0, the average weight was 197.02 grams, at the time of T2 205.43 grams, and at the time of T4 214.98 grams, and in the case of group D the average weight was 247.94 grams, at time T2 256.46 grams, and at time T4 270.63 grams.

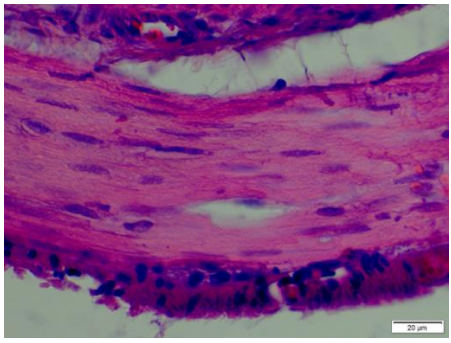

Fig. 2. Normal sigmoid colon (Group A)

At 48 hours after the production of the sigmoid perforation, at the time of T2, according to the planning, we randomly selected 5 subjects from groups B, C and D.

Macroscopically, when entering the peritoneal cavity, it was found in the case of group B the presence of a minimal amount of intraperitoneal fluid with serocitrin appearance, slightly relaxed colic, (fig. 3a) sigmoid perforation covered by intensely adherent intestinal loops (fig. 3b). By comparison, the subjects from group C showed an unfavorable evolution, intraperitoneally presenting both intestinal loops and a relaxed, edematous colic frame (fig. 3c) covering the perforation from which fecal matter is externalized (fig. 3d). Regarding group D, no significant changes were found compared to subjects from group B (figs. 3e, 3f).

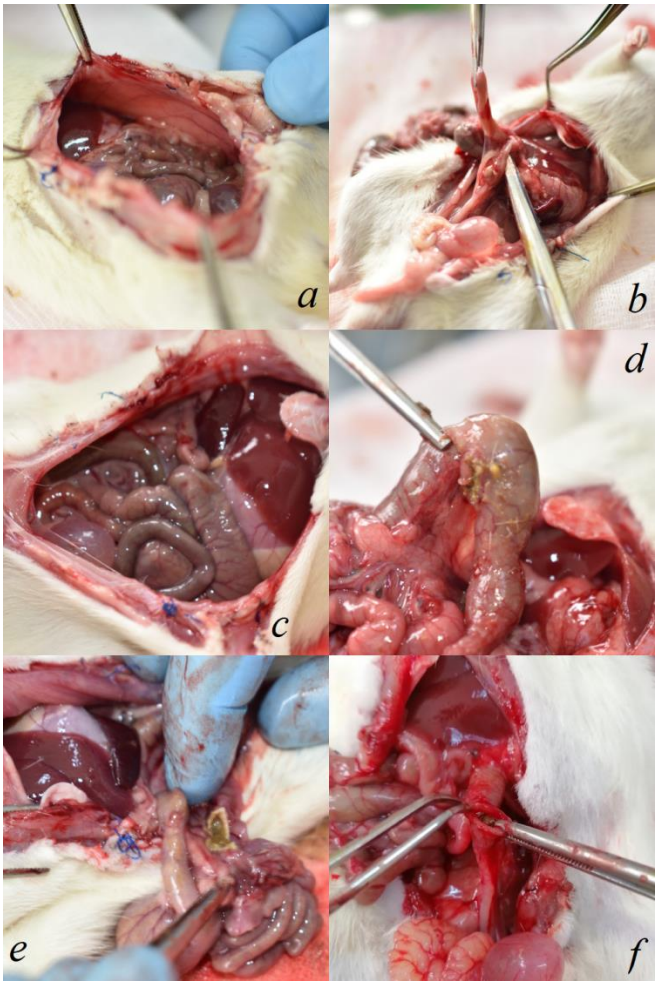

Fig. 3. a) Intraperitoneal appearance in a subject in group B at time T2; b) Intestinal loops adhering to the sigmoid perforation in a subject from group A at time T2; c) Intraperitoneal appearance of a subject belonging to group C at time T2; d) Sigmoid colon perforation with excretion of feces (Group C, T2); e) Intraperitoneal appearance group D at time T2; f) Intraperitoneal appearance group D at time T2.

At time T4, at 96 hours postoperatively, we sacrificed 5 subjects from groups B and C and 4 subjects from group D, one subject from group D died at time T3. Intraperitoneally, in subjects from group B, the minimum amount of serocitrin fluid, relaxed intestinal loops (fig. 4a), check and much relaxed colic frame, and edema are found (fig. 4b). In subjects from group C, distension of the intestinal loops with the presence of the minimum amount of intraperitoneal fluid was reported (fig. 4c), at the level of the perforation of the supple intestinal wall, without inflammatory signs (fig. 4d). The subjects in group D did not show free intraperitoneal fluid, instead, they showed relaxed intestinal loops, with the formation of plastrons at the level of perforation (fig. 4f).

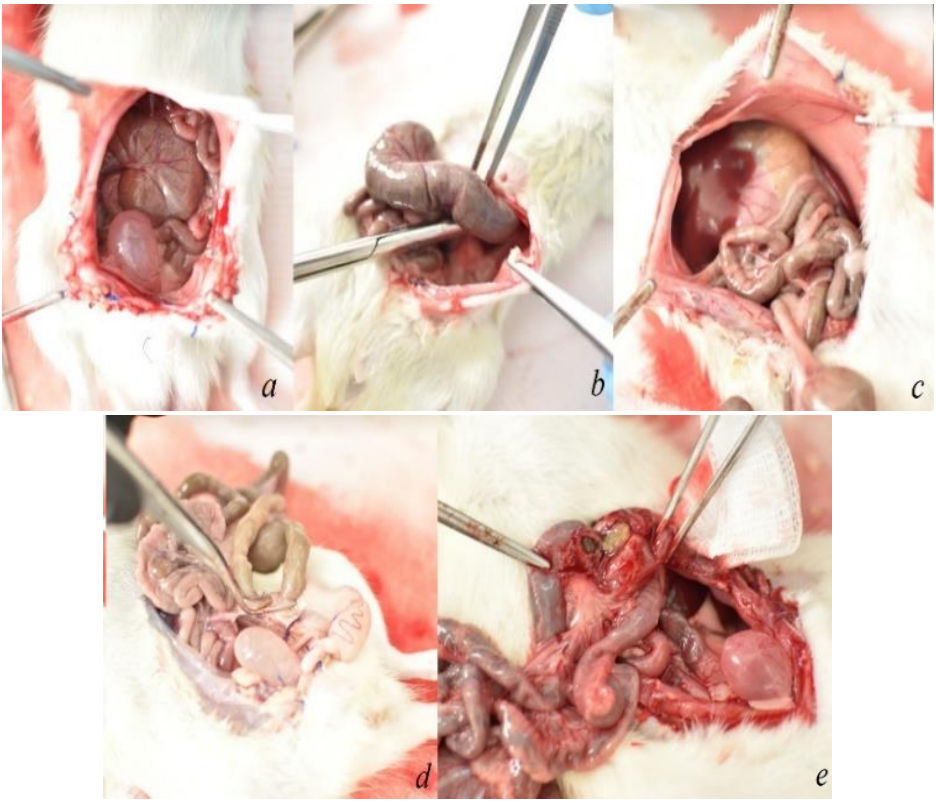

Fig. 4. a) Intraperitoneal appearance group B at time T4; b) Intraperitoneal appearance group B at time T4; c, d) Intraperitoneal appearance group C at time T4; e) Intraperitoneal appearance group D at time T4.

On microscopic examination, at time T2, a better evolution of groups C and D was observed, compared to group B, at the same time, group D showed the least inflammatory changes, at the level of the peritoneum being described as its discrete thickening and the presence of active mesothelial cells (fig. 5a) and at the level of the sigmoid being described thickened serous with vascular hyperemia at the level of the colic wall muscles and rare active mesothelial cells (fig. 5b). Subjects in group C showed serous peritoneum with hyper basophilic active mesothelial cells, hyperplastic lymph nodes, thickened mesenteric adipose tissue, edema with fibroblasts and active macrophages (fig. 5c), sigmoid colon with mesothelial cell activation, hyperemia moderate infiltration of mesenteric adipose tissue with lymphocytes, macrophages and neutrophils (fig. 5d). In group B, the peritoneum showed folding and detachment from adjacent muscles, infiltration rich in macrophages and neutrophils, fragmentation of connective tissue and basement membrane of the peritoneal sheet, mesothelial activity, sub peritoneal edema and fragmentary degeneration of adjacent muscle fibers, (fig. 5e) and at the level of the colon was observed serous bordered by mesothelial cells enlarged in volume, active, mucosa with abundant cellularity (fig. 5f).

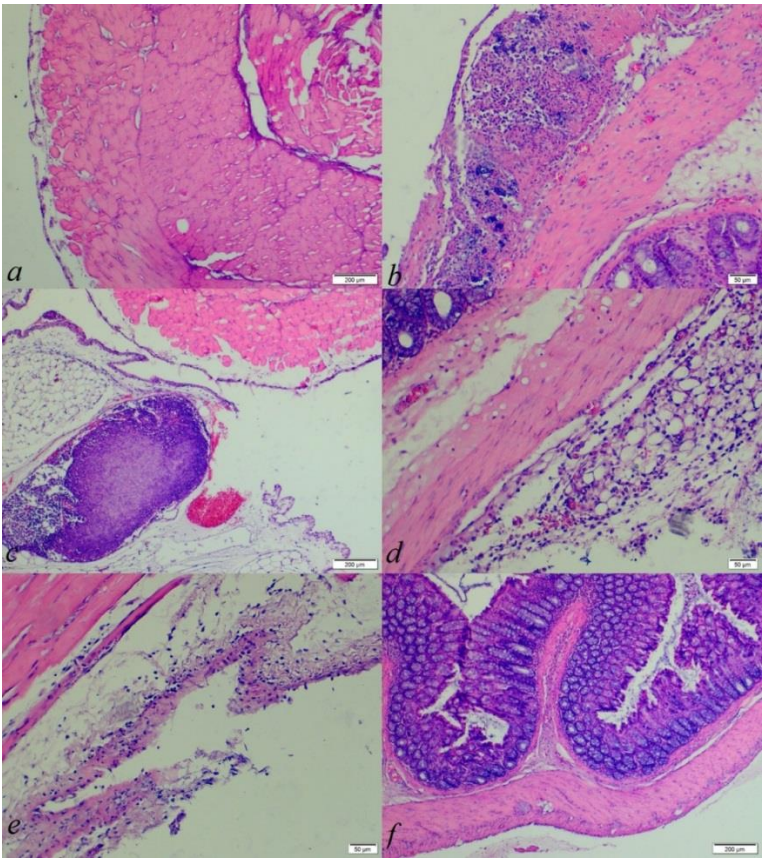

Fig. 5. a) Peritoneum with discrete thickening and the presence of active mesothelial cells, HE X4; b) Thickened serosa with vascular hyperemia in the colic wall muscles and rare active mesothelial cells, batch D, T2, HE, X10; c) Serous peritoneum with hyper basophilic active mesothelial cells, hyperplastic lymph nodes, thickened mesenteric adipose tissue, edematous fibroblasts and active macrophages, batch C, T2, HE X4; d) Sigmoid colon with activation of mesothelial cells, hyperemia of local vessels, with moderate infiltration of mesenteric adipose tissue with lymphocytes, macrophages and neutrophils, group C, T2, HE X10; e) Peritoneum with infiltrate rich in macrophages and neutrophils; fragmentation of connective tissue and basement membrane of the peritoneal sheet; mesothelial activity with sub peritoneal edema and degeneration of adjacent muscle fibers, group B, T2, HE X10; f) Serosa of colon bordered by mesothal cells enlarged in volume, active, mucosa with abundant cellularity, group B, T2, HE X4.

Microscopic analysis of the samples collected at T4 revealed a better evolution of the subjects in group D, so at the level of the parietal peritoneum there are rare active mesothelial cells, increased in volume (fig. 6a), and at the sigmoid without signs of inflammation (fig. 6b). Comparatively, group B showed an unfavorable evolution, so at the level of the peritoneum was detected edematous peritoneal serum edematous, interrupted, infiltrated with neutrophils and macrophages, with hyperemia of the vessels

(fig. 6c) and at the level of the sigmoid colon was detected peritoneal reaction that deforms the visceral peritoneum which is hyperplasia of hyperbasophilic cells, abundantly infiltrated with fibroblasts, neutrophils and macrophages, with edema, vascular hyperemia and capillary neoplasms (fig. 6d). Subjects in group C presented at the level of the peritoneum naked parietal sheet peritoneal, slightly thickened, with a tendency to detach, hyperemic skeletal muscle (fig.6e), and at the level of the sigmoid thickening of the visceral peritoneum with rare active mesothelial cells, adjacent tissue edema, invaded by groups of neutrophils and macrophages (fig. 6f).

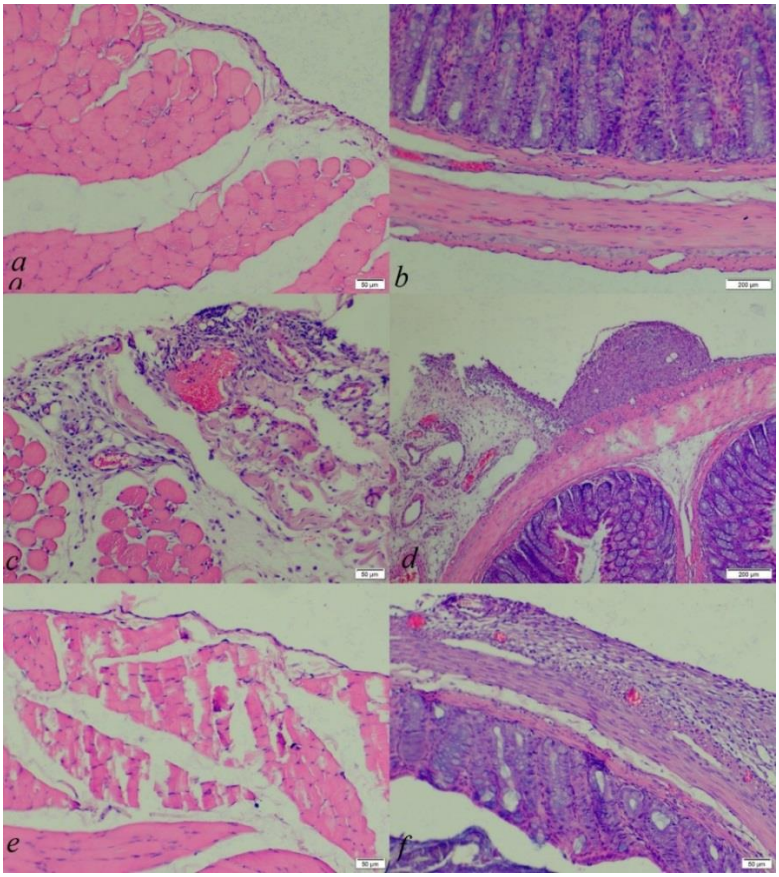

Fig. 6. a) Peritoneum with rare active mesothelial cells, increased in volume, batch D, T4, HE X1; b) Sigmoid colon without signs of inflammation, group D, T4, HE X10; c) Edematous peritoneal serum, interrupted, infiltrated with neutrophils and macrophages, with hyperemia of vessels, group B, T4, HE X10; d) Deformed visceral peritoneum, hyperplasia of hyperbasophilic cells, abundantly infiltrated with fibroblasts, neutrophils and macrophages, with edema, vascular and capillary hyperemia of neoformation, group B, T4, HE X4; e) Bare parietal leaflet, slightly thickened, with a tendency to detach, hyperemic skeletal muscles, group C, T4, HE X10; f) Visceral peritoneum with rare active mesothelial cells, adjacent edematous tissue with hyperemia, invaded by groups of neutrophils and macrophages, group C, T4, HE X1.

All subjects examined at T2 and T4 were euthanized according to internal procedures with an overdose of anesthetic after sampling.

DISCUSSION

In the case of perforation of the colon, mortality is between 11.1 and 31.6% (3, 13-15), studies in the laboratory animal found mortality of up to 80% within 72 hours of the perforation. (16), in our study a mortality of 3.33% was recorded, the death occurring within 72 hours from the time of perforation.

Studies in rats have shown that peritoneal lavage decreases mortality in acute peritonitis, (17, 18) in the absence of any treatment, which can reach up to 100% in 12- to 52-hour intervals. (17, 19) in our study, the mortality at 24 hours, in the case of subjects who did not receive treatment was 0% at 24-48 hours, similar to groups C and D, with the mention that at the time of T3, there was a death in group D, explainable in the context in which studies in rats showed mortality at 8 days of 10% (12).

With the formation of intraperitoneal abscesses, the effects of peritonitis begin to decrease, the clinical evolution being towards an apparent cure (20), in our study, all subjects showed intraperitoneal abscesses, formed by organs adjacent to the perforation, which had a role localization of the lesions, without noticing a significant decrease in macroscopic changes in the peritoneal cavity. At time T2 in all groups the presence of intraperitoneal fluid could be observed, at time T4 the amount of intraperitoneal fluid remained similar in the case of subjects in groups B and C, in the case of subjects in group D the absence of intraperitoneal fluid was found.

Paralytic ileus secondary to acute peritonitis has been explained, according to Stokes' law, as a result of serious inflammation (21) in the first phase, then bacterial toxicity and finally intraperitoneal adhesions (22) The main feature is the distension of intestinal loops (23-26).

In our study, ileus was detected in all subjects at both T2 and T4, with a slight improvement in subjects receiving antibiotic treatment at T4.

Intraperitoneal adhesions are classified by Adhesion grading scale: Score 0 - no adhesions, Score I - Filmy adhesions, Score II - Definitely localized adhesions, Score III - Dense multiple visceral adhesions, Score IV - Dense adhesions extending to the abdominal wall (27, 28). In our study in the case of each group we found in T2 moment score I to II adhesions and in T4 moment score II to III adhesions, with no notable differences between groups.

The inflammatory response of the peritoneum is produced by several steps, (29, 30) characterized by increased blood supply with the accumulation and attraction and infiltration of immune cells, with the accumulation of macrophages, which play a key role in the immune response of the peritoneum, which releases pro and anti-inflammatory factors (30, 31). Macrophages, resident in the peritoneal cavity and sub mesothelial stroma, play a key role in recognizing and digesting foreign matter and the introduction of inflammatory leukocytes into the blood, including monocytes, lymphocytes and neutrophils (30). In response to leukocyte infiltration and activation, mesothelial cells activate and begin to secrete proinflammatory factors (30, 32-35) at the level of the parietal peritoneum as well as at the level of the visceral peritoneum at the level of the affected organ. The exception was group D, in which, at the

time of T4, a minimal inflammatory reaction was found in the visceral peritoneum and the absence of inflammatory phenomena in the parietal peritoneum.

Exaggerated immune responses can lead to angiogenesis, fibrosis and later destruction of the peritoneum, (30, 36) such lesions were also found in our study.

Both meropenem and cefuroxime combined with or without metronidazole are used successfully in treating acute peritonitis with similar results (37, 38).

Our study showed better histopathological results in subjects treated with meropenem, especially at the time of T4, although no noticeable differences were observed macroscopically, and the only death occurred in a subject in group D. Subjects who did not receive antibiotic treatment showed the most important inflammatory changes on microscopic examination.

CONCLUSIONS

Our study proposed a model for simulating acute peritonitis by sigmoid perforation and tracking macroscopic and microscopic changes in both the parietal peritoneum and the visceral peritoneum. Both macroscopic and microscopic changes varied depending on the group, the treatment received, and the individual. From a microscopic point of view, the most important changes were of an inflammatory nature, the most important inflammatory reactions being in the parietal peritoneum. Although no major differences between batches were found in terms of general condition and macroscopic changes, in terms of microscopic changes, meropenem treatment showed remarkably better results, especially at T4. Meropenem is a first-line antibiotic in acute peritonitis secondary to colonic perforation, which together with surgery can reduce the morbidity and mortality of this pathology.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

RESEARCH ETHICS STATEMENT

The research was conducted according to the rules of the Organization for Economic Cooperation and Development (OECD) in good laboratory practice (GLP) and in accordance with the Romanian laws in force and the internal protocols, with the authorization of the Veterinary Authority and the Ethics Committee of the "Cantacuzino" Institute.

A COMPARATIVE STUDY IN THE APPROACH OF INCISIONAL HERNIAS (Abstract): Incisional hernias are one of the most frequent forms of complications derived from postoperative wound complications and must be addressed surgically. One of the best techniques is the Rives-Stoppa technique, which is also suitable for open surgery and minimally invasive procedures. **Material and methods:** We conducted a study to evaluate the results of open or laparoscopic surgery using the Rives-Stoppa method. **Results:** We completed the survey over three years and assessed the outcomes for 49 patients, of which 13 were treated with open surgery and 36 by using the minimally invasive technique, the average age of the patients being 52,02 ± 12,73 years old. **Conclusions:** The results show a significantly more extended hospital stay for the patients with open surgery combined with a considerably higher proportion of complications. **Keywords:** SECONDARY PARIETAL DEFECTS, RIVES-STOPPA TECHNIQUE, ABDOMINAL WALL, EVENTRATION.

Incisional hernias are one of the most frequent post-operatory complications of wounds, varying from 4% to 20% (1). Because the medial incision is the most frequent, most of the hernias are located at this level, some numbers suggesting 70-90% (2).

Initially described by Rives and Stoppa, this technique implies the incision of the skin and subcutaneous tissue, with the visualization of the sack and its release. After its opening, the viability of the content is verified, and intrasaccular and intraperitoneal adherences are dissected. Next, the reconstruction of the parietal wall follows the saccular resection. Next, the posterior fascia of the rectus abdominis is opened on the medial margin, and a retro rectal avascular plane is created through good resection. Here, the mesh is connected to the lateral margin of the muscle, where the vascular and nervous bundles are located.

The extraperitoneal method is done by repairing the hernial defect using extraperitoneal methods without opening the peritoneum (thus avoiding abdominal viscera and forming post-operatory adherences), is based on the procedures used in classic interventions and described by Rives and Stoppa. The techniques were first described in France by Dulucq J.L. (3-5), who used a surgical abutment of the dissection of the peritoneal space, followed by McKernan and Laws in 1993, which used the trocar with a dissecting balloon (6).

The advantage of using these techniques resides in intraabdominal pressure, which acts on the mesh's surface and fixates the

prosthetic material on the muscular plane. As a result, the laparoscopic anatomy of the region is seen differently from the classic anatomy. But, first, the surgeon must identify critical anatomical landmarks for incisional hernias. This study aims to evaluate the differences in recovery time and complications for patients with a hernia that are treated by using classic versus minimally invasive Rives-Stoppa techniques for eventrations.

MATERIAL AND METHODS

The prospective study was conducted on 49 patients treated for eventrations, over three years, between 2018 and 2021. Based on medical characteristics, patients were assigned to either classic or minimally invasive intervention (laparoscopic or endoscopic).

At the initial consult, we measured the socio-medical characteristics of the patients (age, sex, environment, weight, localization of the hernia, and comorbidities). Then, following the surgical procedures, we followed up with the patients and gathered data on their evolution, hospitalizations, and complications.

We used descriptive statistics, mean and standard deviation for continuous, numerical values, and counts (with percentages) for categorical variables. The tests used for determining the statistical significance of the results were adapted to the type of variable based on the existing general recommendations (7). For example, a "p" value less than 0.05 was considered statistically significant.

RESULTS

Characteristics of the sample

Table I summarizes the characteristics of the patients at admission. As can be observed, there are no statistically significant differences between the two groups of patients that underwent Rives-Stoppa intervention compared to the ones with minimally invasive interventions.

TABLE I.
Characteristics of the patients

	Total (49)	Minimally invasive (36)	Classic(13)	p-value
Age				
Mean ± SD	52.02 ± 12.73	50.33 ± 13.71	56.69 ± 8.24	0.12
Sex				
Male	25 (51%)	19 (52.8%)	6 (46.2%)	0.68
Female	24 (49%)	17 (47.2%)	7 (53.8%)	
Environment				
Urban	37 (75.5%)	28 (77.8%)	9 (69.2%)	0.54
Rural	12 (24.5%)	8 (22.2%)	4 (30.8%)	
Weight				
Mean ± SD	88.35 ± 15.55	90.39 ± 14.89	82.69 ± 16.51	0.13
Localization				
Supraumbilical	23 (46.9%)	18 (50%)	5 (38.5%)	0.58
Umbilical	10 (20.4%)	6 (16.7%)	4 (30.8%)	
Subumbilical	14 (28.6	10 (27.8%)	4 (30.8%)	
Inguinal	2 (4.1%)	2 (5.6%)	0 (0%)	
Size of the defect (cm)				
Mean ± SD	12.22 ± 6.4	10.03 ± 4.8	18.31 ± 6.5	<0.01

The average age of the patients was 52.02 years, with a standard deviation of 12.73 years. We observed that the average for the patients with minimally invasive interventions was more than six years smaller than those for whom the Rives-Stoppa intervention was used.

Even though there was a difference in the proportion of males and females, with a higher percentage of males being operated on using minimally invasive techniques, the results were not statistically significant.

At first sight, the proportion of patients according to the environment might give the impression that there is a significantly larger of patients living in urban areas. However, for the whole sample of patients, 69.2% were from urban areas. Considering where the patients come from, an acceptable percentage is in South-East Romania. According to official data, about 70% of the people live in urban areas, thus making these numbers normal. Regarding the localization of the hernia, again, there are no statistically significant differences (p=0.58) between the two groups. For minimally invasive interventions, half of them were supra-umbilical. When the hernia was in the umbilical area, the percentage of Classic-type interventions was almost double in frequency (30.8%) compared to the frequency of umbilical hernia for patients treated using minimally invasive techniques (16.7%). Also, for larger hernias, the classic intervention was preferred. The average size of the abdominal wall defect is almost double for patients treated using traditional interventions. When comparing the frequency of comorbidities at admissions, we observe essential differences in proportions regarding high blood pressure and obesity, cases in which minimally invasive techniques were preferred (tab. II). However, differences were not statistically significant (p=0.1).

TABLE II.
Comorbidities

	Classic	Minimally Invasive	Total
Atrial Fibrillation	1 (7.7%)	0 (0%)	1 (2%)
Cardiac Insufficiency	1 (7.7%)	2 (5.6%)	3 (6.1%)
Diabetes Mellitus Type 1	1 (7.7%)	0 (0%)	1 (2%)
Diabetes Mellitus Type 2	1 (7.7%)	0 (0%)	1 (2%)
High Blood Pressure	2 (15.4%)	9 (25%)	11 (22.4%)
Obesity	2 (15.4%)	13 (36.1%)	15 (30.6%)
Pulmonary Tumor	1 (7.7%)	0 (0%)	1 (2%)
Thyroiditis	0 (0%)	1 (2.8%)	1 (2%)
No comorbidity	4 (30.8%)	11 (30.6%)	15 (30.6%)

Post-surgery evolution

We analyzed the way patients evolved following the surgical intervention. We observed an almost four times higher percentage of complications following the Classic techniques than minimally invasive

procedures. The difference was statistically significant (p=0.01), suggesting an increased association between the Classic method and the appearance of complications (fig. 1).

When analyzing the days of hospitalization, the mean value for the number of hospitalization was 2.72 ± 0.944 days for the minimally invasive techniques and significantly higher, with an average of 4.69 ± 1.18 days for the patients for which Classic styles was used (tab. III). The difference was statistically significant, with p<0.001.

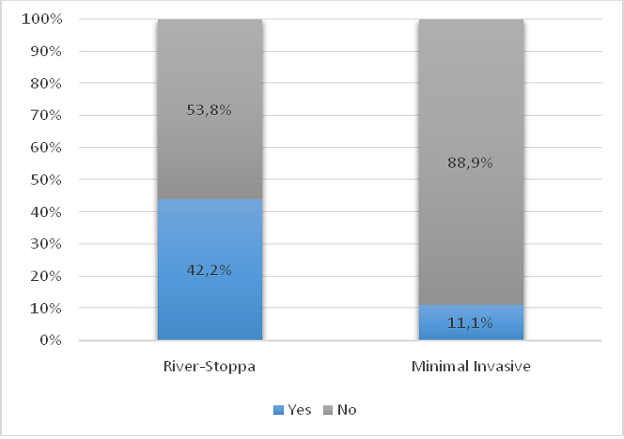

Fig. 1. Proportion of complications after the surgical intervention

TABLE III.

Descriptive analysis – days of hospitalization

Days of hospitalization	Type of Surgical Intervention		
	Classic	Minimally Invasive	Total
N	13	36	49
Mean	4.69	2.72	3.24
Std. Deviation	1.182	.944	1.331
Median	4.00	2.50	3.00
Minimum	3	2	2
Maximum	7	5	7
Skewness	1.065	1.465	1.075

DISCUSSION

Our study focused on identifying differences in the evolution of patients with an incisional hernia, depending on the surgical interventions used (Classic or Minimal Invasive). The Rives-Stoppa technique offered excellent long-term results in patients with large hernias (primary of incisional) (8).

Our study's sample population consisted of patients with different degrees of incisional hernias. We observed no statistically significant differences in patients within the arms of the study. Even though there is a very high percentage of patients within the urban area, this is considered normal for where the study took place, so we cannot say that there are issues related to health

inequalities, as observed in other studies or on different types of pathologies. (9, 10).

The primary outcome of the study was the presence of post-surgery complications.

Complications were observed in a relatively large number of patients treated with Classic intervention (42.2%) compared to Minimally Invasive methods (11.1%). The Classic intervention represented the complications caused by suppurations, hematomas, or seromas. In the case of Minimally Invasive interventions, the complications were described by local pain and thread granuloma.

Considering that the patients presented with incisional hernias, with one-quarter previously treated for hernia, we believe the observed results are within typical values. Other studies reported similar rates of complications, with significant variability (11, 12). Differences in the percentage of complications may also appear because of the difference in the size of the treated eventration, open surgery being preferred in the case of more significant abdominal wall defects.

The economic aspect is also essential when analyzing surgery outcomes. For example, using Minimally Invasive techniques, not only did the patients have significantly fewer complications, but the length of hospital stays was significantly reduced, from a median of 4 days (open surgery) to a median of 2.5 in the case of Minimally Invasive techniques, this represents one of the significant advantages of Minimally Invasive techniques (13, 14).

The present study adds to the existing literature by comparing surgical techniques for incisional hernias. Compared to open surgery, we demonstrated that minimally invasive procedures have better results in terms of recovery time and lack of complications.

We would have compared patients with eventrations of similar sizes for a better comparison. Also, the study focuses on immediate complications without considering possible recurrent hernias that can appear in time.

CONCLUSIONS

The minimally invasive approach offers shorter recovery time, thus decreasing the length of the hospitalization, with all the associated benefits and lower percentages and seriousness of the complications.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

EXCELLENT LONG-TERM NEGATIVE PREDICTIVE VALUE OF CAPSULE ENDOSCOPY IN SUSPECTED ISOLATED SMALL BOWEL CROHN'S DISEASE (Abstract): There is no unique diagnostic test for Crohn's disease (CD), and the diagnosis of isolated small bowel Crohn's disease (SBCD) is even more challenging, due to non-pathognomonic clinical picture and low availability of accurate exploration methods. Small bowel capsule endoscopy (SBCE) revolutionized the approach of middle gastrointestinal tract, becoming the first investigation tool when small bowel pathology is suspected. The **aim** of our study was to assess the value and safety of SBCE in diagnosing isolated SBCD. **Materials and methods:** We retrospectively studied the patients undergoing SBCE for suspected isolated SBCD, in a six-year period, including in our analysis only the patients with a minimum of 18-month follow-up period. We assessed the global diagnostic yield (DY) of SBCE, as well as its yearly variation in time over the six-year period, and the complication rate. Subsequently, analyzing follow-up data, positive and negative predictive values were assessed. **Results:** 78 patients were investigated by SBCE for suspected isolated SBCD, mostly men (60.3%), with age ranging from 20 to 69 years old. SBCE showed lesions compatible with the diagnosis of SBCD in 49 patients, corresponding to a specific diagnostic yield of 62.8%, while for the remaining 29 patients (37.2%), no suggestive lesions were found. Following additional investigations, three of the 49 patients initially thought as having isolated SBCD were reclassified as intestinal lymphoma, eosinophilic gastroenteritis and intestinal tuberculosis, respectively, corresponding to a positive predictive value of 93.8%. During follow-up, none of the 29 patients with negative SBCE was diagnosed with CD, corresponding to a negative predictive value of 100%. We found a progressively increase of the diagnostic yield over time (from 42.6% in the first year to 70.2% in the last year of the analyzed period), corresponding the most probably to the refinement of the indication. **Conclusions:** SBCE has good DY and a high positive predictive value for isolated SBCD. However, it remains a purely visual technique with no capability of taking biopsies, so final diagnosis needs confirmation by additional investigations. Nevertheless, SBCE has a 100% long-term negative predictive value, being an excellent tool for ruling out isolated SBCD. **Keywords:** CAPSULE ENDOSCOPY, SMALL BOWEL, CROHN'S DISEASE.

Crohn's disease is a chronic inflammatory bowel disease, with various phenotypes and different particularities in each individual's clinical picture. Crohn's disease may affect any part of the gastrointestinal tract, the most frequent being the ileocecal localization - when both terminal ileum and part of colon are involved, while in approximately one third of cases, patients have only small bowel involvement (1). As there is no unique gold standard diagnostic test for Crohn's disease, the positive diagnosis is based on a combination of clinical evaluation, together with biological, imaging, endoscopic and histologic data (2). Moreover, due to the fact that clinical manifestations are not always pathognomonic, and that accurate exploration methods for the small bowel are not universally available, the diagnostic of isolated SBCD is even more challenging.

However, the introduction into the clinical practice of the capsule endoscopy, which has become the first investigation tool when small bowel pathology is suspected, has revolutionized the approach of the middle gastrointestinal tract (3). SBCE is nowadays consensually indicated in several IBD situations, as suspected Crohn's disease, evaluation of extension and activity of known CD, assessing the response to therapy, identifying the postoperative CD recurrence, and evaluation of unclassified colitis (4). The use of SBCE is justified by its advantages compared to other investigation methods; firstly, the safety and the non-invasiveness versus enteroscopy, and the superior diagnostic yield compared to imaging methods as enteroclysis, computed tomography-enterography, and magnetic resonance-enterography for incipient lesions (5-7). Nevertheless, SBCE has its limits, the main one being the inability of taking biopsies. Thus, SBCE remains a visual technique, and in some cases, for arriving at the final diagnosis, supplementary investigations might be necessary. Consequently, the discriminative power of SBCE as a single technique for exploring the small bowel is a question of debate. In this context, we aimed to assess the value of SBCE in diagnosing isolated SBCD. In the same time, considering that CD is one of the conditions predisposing patients to the retention risk, we also aimed to evaluate the safety of SBCE in investigating patients with suspected isolated SBCD.

MATERIAL AND METHODS

Patients

We retrospectively studied the patients undergoing SBCE for suspected isolated SBCD, in a six-year period (January 1st2016 – December 31st2021), in the Institute of Gastroenterology and Hepatology. We included in our analysis patients with clinical, biologic and/or imaging suspicion of CD, with no diagnostic findings at conventional ileocolonoscopy, who were followed after SBCE exploration for at least 18 months period.

Methods

We assessed the performance parameters of SBCE, as well as the complication rate.

The performance parameters were the diagnostic yield (DY), defined as number of capsule endoscopy exams with positive findings from the total number of investigations, the positive prediction value (PPV), defined as ratio of patients truly diagnosed as positive to all those who had positive results, and the negative predictive value (NPV), defined as the ratio of subjects without disease to all those who had

negative test results. Both PPV and NPV were retrospectively assessed, by analyzing follow-up data.

All patients were investigated after contraindications were excluded, and every patient signed the informed consent for SBCE prior to the investigation. The diagnostic work-up was conducted following the actual guidelines for the use of SBCE. Before SBCE, all patients underwent colonoscopy, which did not CD lesions.

The preparation was made with two liters of polyethylene-glycol the evening before the procedure, and the patients fastened overnight. The third-generation endoscopic capsule for small bowel examination (PillCam SB3) manufactured by Given Imaging, Yoqneam, Israel, was used. Interpretation of data was made with RAPID™ reader software.

The diagnostic of Crohn's disease was sustained according to Mow's criteria – more than three ulcerations, in the absence of nonsteroidal anti-inflammatory drugs (NSAIDs) administration (8). Anyway, patients with recent (four weeks or less) history of NSAIDs use were excluded from the analysis. For all the patients with Mow's criteria fulfilled, the Lewis score (LS) were afterwards assessed. The Lewis score is an incorporated software algorithm which sums up the points assigned to three characteristic findings – strictures, ulcers, fistula in the three segments of the small bowel, and classify the severity of inflammation into three categories: insignificant, mild or moderate-to-severe (9).

Complications of CE were noted. Incomplete examinations were not included in the study.

Statistical analysis was conducted using the *SPSS version 17.0 software* (SPSS Inc., Chicago, IL, USA).

RESULTS

Patients' characteristics

In the analyzed six-year period, 78 patients underwent SBCE for suspected isolated CD. Their characteristics are presented in the first table.

TABLE I.

Clinical characteristics of patients, findings at SBCE and follow-up data

	Total number of patients = 78
Age, years, mean ± SD	43 ± 12.5
Range, years	20-69
Gender ratio	31/47
Women/Men, n (%)	(39.7%/60.3%)
SBCE exam results	
Positive for CD, n (%)	49 (62.8%)
Negative for CD, n (%)	29 (37.2%)
Follow-up data	
CD confirmed	46/49 (93.8%)
CD ruled out	29/29 (100%)

Diagnostic yield

SBCE showed lesions compatible with the diagnosis of CD in 49 patients, corresponding to a diagnostic yield of 62.8%. For the remaining 29 patients (37.2%), no suggestive lesions were found, and consequently CD was ruled out.

We found a progressively increase of the diagnostic yield over time (from 42.6% in the first year to 70.2% in the last year of the analyzed period), corresponding the most probably to the refinement of the indication.

Lewis score

For the inflammation quantification, the Lewis score was used; 22 patients presented a score between 135 and 790, being classified as having mild inflammation, while the remaining 27 patients had a score > 790 points, corresponding to moderate-to-severe inflammation.

Positive predictive value

Analyzing follow-up data, we found that three of the 49 patients initially considered as having isolated SBCD were consequently further explored, and eventually a different diagnosis was made, corresponding to a positive predictive value of 93.8%. Out of the three patients, one patient was diagnosed with eosinophilic enteritis, one patient was confirmed as having intestinal T-cell lymphoma, and one patient had intestinal tuberculosis. All the three patients had a baseline moderate-to-severe inflammation, according to the LS.

Negative predictive value

During the follow-up period, none of the 29 patients with negative SBCE exam was diagnosed with CD, corresponding to a negative predictive value of 100%.

Complications

One case of capsule retention was noted (retention rate 1.28%), due to an ileal stricture in a patient with small bowel CD. Medical treatment was not successful, so the patient underwent surgery; stricturoplasty, as well as removal of retained capsule, were performed.

DISCUSSION

SBCE has emerged as a valuable tool for the diagnosis of CD. The ability to directly visualize the intestinal mucosa allows a comprehensive evaluation of the small bowel. Because CD may involve only small bowel segments, SBCE is a particularly valuable method in cases where other diagnostic methods, such as conventional endoscopy, are not contributive.

Studies have reported diagnostic yields of SBCE ranging from 50% to 80%, generally superior compared to other diagnostic modalities (5, 7, 10, 11). Ileocolonoscopy with biopsy remains the gold standard for the diagnosis of CD (4), but if it is normal, it must be followed by the SBCE in the absence of obstruction. A large meta-analysis showed superiority of SBCE compared to small bowel follow-through (52% *vs.* 16%), computed tomography-enterography (68% *vs.* 21%), and ileocolonoscopy (47% *vs.* 25%) (7). SBCE also proved its significantly higher sensitivity for incipient lesions, especially in the jejuni and ileum, compared to magnetic resonance-enterography, as a recent Spanish study showed (77% *vs.* 48%) (12).

Our study showed a global diagnostic yield for isolated CD of 62.8%, proving the value of SBCE in this particular type of CD patients, with exclusive small bowel involvement, where conventional endoscopy has limited role. The yearly analysis of the DY showed a higher DY over time (up to 70.2%), which we interpret as refinement of the indication.

Even if SBCE is a sensitive tool for mucosal abnormalities, one important limitation consists in the lack of definitive diagnostic criteria for CD. Mow's criteria are generally used for diagnosis, while other scoring systems, as Lewis score and, more recently, the Capsule Endoscopy Crohn's Disease Activity Index, are useful especially for disease monitoring and treatment guidance (13). Moreover, for suspected SBCD, it has as drawback a relative lack of specificity. In our analysis, three patients initially considered as having isolated SBCD were further explored and reclassified. They underwent SBCE for suspected CD based on their clinical picture; abdominal pain, chronic diarrhea, weight loss and anemia are overlapping symptoms for CD, eosinophilic enteritis, intestinal tuberculosis and intestinal lymphoma. SBCE findings consisted in oedema, hyperemia, erosions and superficial and deep ulcerations, which may appear

both in CD and in other inflammatory or non-inflammatory conditions. All the three patients had a baseline moderate-to-severe inflammation, according to the LS. Notably, all the three patients had a baseline moderate-to-severe inflammation, according to the Lewis score; however, the most appropriate role of the Lewis score is monitoring established CD. Additionally, imaging data may be similar; for both eosinophilic gastroenteritis and lymphoma, entero-CT showed similar SB wall modifications. Following the final diagnosis, made by device-assisted enteroscopy with biopsy, different therapeutic strategies were applied.

Indeed, a main limitation of SBCE is its inability of taking biopsies, while a definite diagnostic of CD would require, in order to be considered beyond any doubt, histologic confirmation. Small bowel ulcerations are not pathognomonic for CD; even they are a common finding in CD and the diagnostic criteria rely on their presence, they however may appear in a variety of other small intestine disorders, such as: infectious enteritis - like intestinal tuberculosis or cytomegalovirus infection, NSAID enteropathy, eosinophilic enteritis, ischemic enteritis, or intestinal lymphoma (14). Moreover, mucosal erosions may be found even in approximately 10% of healthy subjects (15). Precautions must be taken before SBCE, such as stopping NSAIDs at least four weeks before the investigation. Also, sometimes, further evaluation modalities must be considered. Enteroscopy with biopsy is a complementary investigation, which could ensure a final diagnosis. SBCE acts as a non-invasive evaluation tool, guiding the decision and the access way for a further enteroscopy. Current guidelines recommend upper or lower device-assisted enteroscopy after SBCE, allowing targeted biopsies.

In our study, follow-up data showed that none of the patients with negative SBCE exam was diagnosed afterwards with CD. Basically, normal SBCE can rule out CD with maximum confidence. As SBCE is recommended as a first line test for SB pathology suspicion, its capability to exclude CD makes it a very reliable tool in CD work-up.

SBCE is generally considered a safe technique; however, retention can occur, if narrowing, stricture, or obstruction of a certain intestinal segment exists. Other complications are extremely rare. The retention rate varies according to the indication, from 1%-2% in patients with suspected CD, up to 10-13% in patients with known CD (16). In our study, the retention rate was 1.28%, similar to other reports. Nevertheless, concerning capsule retention in suspected CD, several comments should be made. Apart known strictures, all other contraindications may be considered relative, and even in the event of retention with no response to conservative management, surgery will solve both the capsule impaction and the obstructive lesion, allowing also a definite histologic diagnosis. Patency capsule is indicated in order to confirm the permeability of gastrointestinal tract only when there is a clinical suspicion of small bowel obstruction, otherwise it is not routinely advised (4). Showing a retention rate close to that reported for obscure gastrointestinal bleeding, which remains the most common indication - pooled retention rate 1.2%, as reported by a systematic review by Liao *et al* (17), SBCE in suspected CD appears to be a safe technique.

CONCLUSIONS

SBCE has a good diagnostic yield and a good positive predictive value for isolated

SBCD. It is a safe first line tool in suspected CD, with low retention rate. However, it is a purely visual technique with no capability of taking biopsies. Hence, its results should be interpreted in conjunction with other relevant clinical data, and the final diagnosis needs confirmation by additional investigations. Definitive diagnostic criteria for CD are still lacking. Nevertheless, SBCE showed a very high clinical accuracy for excluding CD. With a 100% long-term negative predictive value, SBCE emerges as an excellent tool for ruling out isolated SBCD.

PREDICTING INTRAUTERINE GROWTH RESTRICTION: A PILOT STUDY WITH FEED-FORWARD BACK PROPAGATION NETWORK (Abstract): The prediction of intrauterine growth restriction (IUGR) represents a challenge for obstetricians throughout pregnancy, and the use of artificial intelligence could improve its screening. The **aim** of this pilot study was to prospectively design and test a Feed-Forward Backpropagation neural network (FFBPN) for the prediction of IUGR and its subtypes. **Materials and methods:** Between January and September 2023, we included 108 pregnant patients with singleton pregnancies who underwent conventional first trimester screening. Clinical and paraclinical data was used to construct a FFBPN, and its predictive performance was assessed using a sensitivity analysis. **Results:** Our results indicated that the FFBPN predicted the development of IUGR during pregnancy with a sensitivity (Se) of 94.7%, specificity (Sp) of 97.7%, and a false positive rate of 2%. The value of the area under the curve for this neural network was 0.978. On the other hand, when used for the prediction of IUGR subtypes, the FFBPN achieved lower predictive performance. Also, the sensitivity analysis revealed that the FFBPN could better predict early IUGR, with a Se of 71.4%, Sp of 94%, and accuracy of 90.7%. **Conclusions:** The FFBPN could be an important tool for the prediction and stratification of various disorders, including IUGR. **Keywords:** INTRAUTERINE GROWTH RESTRICTION PREDICTION, NEURAL NETWORK, FEED-FORWARD BACKPROPAGATION.

Intrauterine growth restriction (IUGR) is a condition described as a fetal growth rate that is less than normal based on race and gender (1). Although there are slight variations between the two, the words IUGR and small for gestational age (SGA) are frequently used interchangeably. SGA is diagnosed when the birth weight is less than the population norms on the growth charts (less than the 10th percentile for that gestational age) (2).

SGA refers to birth weight without considering in-utero growth. An IUGR newborn, on the other hand, may have an ac-

ceptable gestational weight but may have experienced any in-utero growth retardation as a result of a perinatal injury (3). It is important to note that a neonate with a birth weight less than the tenth percentile can be SGA but not an IUGR, whereas a neonate with a birth weight greater than the 10th percentile can be an IUGR (4).

Every year, an estimated 13.7 million newborns are born at term with low birth weight (LBW), accounting for 11% of all neonates delivered in developing nations (5). When compared to industrialized countries, this incidence is six times higher. IUGR accounts for 23.8% of all infants, or nearly 30 million every year. The prevalence of IUGR varies by country, population, and race, and it rises with decreasing gestational age. Asia bears the heaviest burden of these IUGR neonates, accounting for nearly three-fourths of all affected infants, followed by Africa and Latin America (5).

The current literature outlined multiple risk factors for IUGR such as race and maternal age (below 16 and above 35 years), low socioeconomic status, various maternal illnesses that impact blood circulation can decrease uteroplacental blood flow (i.e. hypertension, diabetes, chronic renal disease, thrombophilia, systemic lupus erythematosus, antiphospholipid syndrome, sickle cell disease, infections) (6-8).

Artificial reproductive technologies (ART) use increases the incidence of IUGR in both singleton and multiple gestation pregnancies (9). Low pre-pregnancy weight and pregnancy weight growth put women in the lowest quartile at the highest risk of having an IUGR fetus (10). Finally, smoking, drinking, drug use, and certain living conditions increase the risk of IUGR. Placental (abnormal placentation and inflammation) and fetal (genetic, metabolic or infectious disorders) risk factors should also be taken into consideration for the screening of IUGR (11-13).

Besides maternal-fetal characteristics, it is important to note that several ultrasound and chemical biomarkers have been included in the screening of IUGR. These include uterine artery Doppler pulsatility indexes, placental growth factor (PlGF), placental protein-13 (PP-13), soluble FM's-like tyrosine kinase-1 (sFlt-1) or vascular endothelial growth factor (VEGF) (14, 15).

IUGR can be defined and classified using the Delphi consensus (16), that is based on EFW and abnormal fetoplacental Doppler parameters: into early IUGR (< 32 weeks of gestation), and late IUGR (≥ 32 weeks of gestation).

Although current conventional antenatal screening of IUGR has a good predictive performance determined in numerous studies and meta-analyses, there are important nuances that can influence these results, and are represented by individual genetic potential, epigenetic influence, specific growth charts, or various definitions of IUGR. Thus, it is important to optimize the current screening strategies in a cost-effective manner in order to offer the best results with minimal efforts.

In the last decade, the artificial intelligence approaches such as machine learning algorithms and artificial neural networks have been successfully used for the prediction of a variety of medical disorders such as small for gestational age fetuses, preeclampsia, HELLP syndrome, seropositivity for hepatitis viruses, (7, 17, 18). Their results are encouraging, many of

them obtaining good predictive performances. In this study we aimed to design and test a Feed Forward Backpropagation neural network (FFBPN) for the prediction of IUGR and its subtypes.

MATERIALS AND METHODS

We performed a prospective observational study at "Cuza-Voda" Clinical Hospital of Obstetrics and Gynecology, Iasi, Romania, between 3rd of January 2023 and 10th of September 2023. The study included pregnant patients with singleton pregnancies who underwent conventional first trimester screening between 11 and 13+6 weeks of gestation.

The exclusion criteria included pregnancies with multiple fetuses, maternal age below 18 years, inaccurate dating of gestational age in the first trimester, abortions in the first and second trimesters, fetal death inside the womb, loss of follow-up, incomplete medical records, or the mother's inability to provide informed consent.

The study was carried out as part of the "Net4SCIENCE: Network for Applied Doctoral and Postdoctoral Research in the Fields of Smart Specialization - Health and Bioeconomy" project, with project code SMIS: 154722. Ethical approval for the study was obtained from the Institutional Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy from Iasi (No. 151/13 February 2022).

All patients underwent ultrasound examination between 11 + 0 and 13 + 6 weeks of gestation by certified obstetricians using an E8/E10 (General Electric Healthcare, Zipf, Austria) scanner to measure crown–rump length (CRL) and nuchal translucency (NT) of the embryo as well as the maternal mean uterine artery pulsatility index (UtA-PI).

A 5 mL blood sample was collected from patients and was stored at at -20°C until we determined the serum levels of human chorionic gonadotropin (β-HCG), pregnancy associated plasma protein-A (PAPP-A), PlGF, and PP-13 using Brahms Kriptor analyzer (Thermo Fisher Scientific, Germany) and quantitative sandwich ELISA. Multiple of medians (MoM) values were calculated for all these markers, and were used for further data analysis. We also calculated the mean arterial pressure with a calibrated Omron device, and we transformed it in MoMs.

This study evaluated data from 108 pregnant patients that included demographic data, body mass index (BMI), smoking status, personal and family history of adverse pregnancy outcomes, maternal comorbidities, gestational age at IUGR detection, gestational age at birth, birthweight, and Apgar score.

The primary outcome of our study was represented by the detection of IUGR, while the secondary outcomes were represented by IUGR subtypes: early and late IUGR.

In the first step of our statistical analysis, we used descriptive statistics and comparisons of categorical variables (Pearson's χ^2 test) or continuous variables (student t test) for evaluated the differences between the main group: group 1 (with IUGR, n= 19 patients) and group 2 (control, n= 89 patients). *P* values under 0.05 were statistically significant. STATA SE (17, 2023, StataCorp LLC, College Station, TX, USA) was used for these analyses.

Our second phase involved creating of a FFBPN for the prediction of IUGR and its

subtypes that included maternal characteristics (age, BMI, smoking status, adverse pregnancy outcomes, comorbidities), MAP, and serum biomarkers (BHCG, PAPP-A, PlGF, and PP-13). Five-fold cross validation was performed on 80% testing and 20% training data.

A sensitivity analysis was done to characterize the predictive performance of the FFBPN for IUGR and its subtypes (early IUGR- 7 patients, and late IUGR- 12 patients). The sensitivity (Se), specificity (Sp), false positive rate (FPR), Matthews correlation coefficient, accuracy, precision, and F1 score were determined. The FFBPN was built and analyzed in Matlab (version R2023a, The MathWorks, Inc., Natick, MA, USA) (fig. 1).

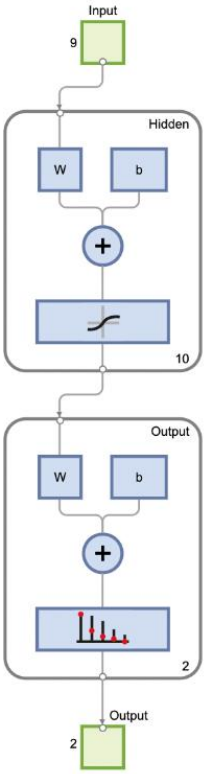

Fig. 1. Architecture of a FFBPN that comprises 10 neurons in the hidden layer. (FFBPN: feed-forward backpropagation neural network)

RESULTS

This study enrolled 108 pregnant patients that underwent first trimester screening. Their demographic and clinical characteristics are presented in table I. Both groups were relatively homogenous considering their clinical characteristics, and we could not find any statistically significant difference between both groups regarding their age (p= 0.32) or BMI (p= 0.76).

On the other hand, the patients who later developed IUGR presented significantly higher rates of smoking during pregnancy

(p= 0.007), autoimmune disorders (p= 0.02) or a personal history of adverse pregnancy outcomes such as intrauterine growth restriction, preeclampsia, abnormal placentation, preterm birth or premature rupture of membranes (p= 0.02).

TABLE I.

Demographic and clinical characteristics of patients included in the study

Clinical characteristics	IUGR group (n= 19 patients)	Control group (n= 89 patients)	*p* value
Age, years (mean ± SD)	25.16±4.32	27.13±3.22	0.32
BMI, kg/m^2, (mean and standard deviation)	23.25± 2.81	23.56± 3.16	0.76
Smoking habit (n/%)	Yes= 6 (40%)	Yes= 8 (9.4%)	0.007
Diabetes (n/%)	Yes= 1 (5.2%)	Yes= 2 (2.2%)	0.46
History of chronic hypertension (n/%)	Yes= 2 (13.3%)	Yes= 2 (2.7%)	0.08
History of autoimmune disorders (n/%)	Yes= 2 (13.3%)	Yes= 1 (1.1%)	0.02
Chronic kidney disease (n/%)	Yes= 0 (0%)	Yes= 2 (2.7%)	0.47
History of adverse pregnancy outcomes (n/%)	Yes= 4 (21%)	Yes= 5 (5.6%)	0.02

IUGR- intrauterine growth restriction, SD- standard deviation, n- number of patients, BMI- body mass index.

A comparison between the main groups regarding the MoM values of the biochemical markers and MAP is presented in table II and figure 2. Our results indicated a statistically significant difference between the two groups regarding the mean serum value of PlGF (p< 0.001) and PP-13 (p< 0.001). Other biomarkers and the MAP did not significantly differ between the two groups.

TABLE II.

Group comparisons of first trimester biochemical markers and mean arterial pressure.

Marker	IUGR group (n= 15 patients)	Control group (n= 180 patients)	*p* value
β-HCG, MoM (mean ± SD)	0.96± 0.15	1.14± 0.44	0.16
PAPP-A, MoM (mean ± SD)	0.81± 0.33	1.04± 0.57	0.06
PlGF, MoM (mean ± SD)	0.68± 0.14	1.26± 0.24	<0.001
PP-13, MoM (mean ± SD)	0.67± 0.16	1.08± 0.43	<0.001
MAP, MoM (mean ± SD)	1.05± 0.08	1.05± 0.06	0.53

IUGR- intrauterine growth restriction, SD- standard deviation, n- number of patients, MoM- multiples of median, β-HCG- beta-human chorionic gonadotropin, PAPP-A- pregnancy-associated plasma protein-A, PlGF- placental growth factor, PP-13- placental protein 13, MAP- mean arterial pressure.

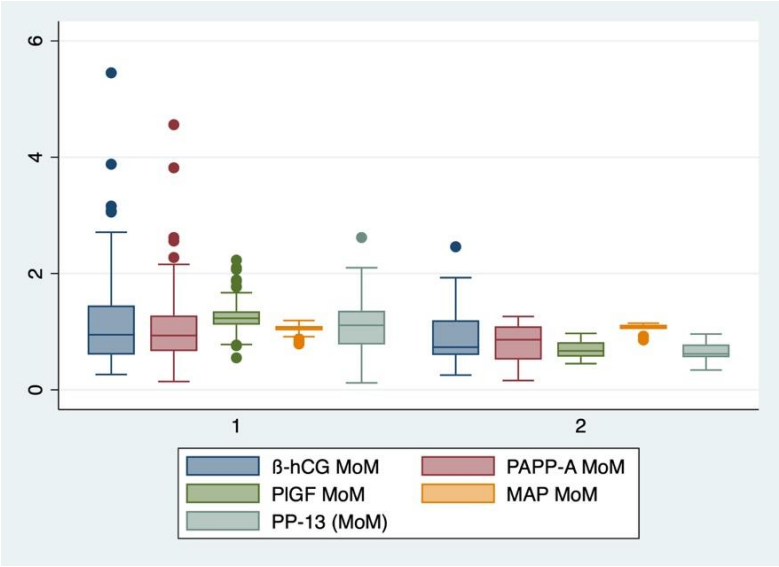

Fig. 2. Boxplot representing the comparisons of individual first trimester markers between groups. (1- control group, 2- IUGR group, 3- PE group, 4- PE and IUGR group).

In the second stage of our analysis, we determined the predictive performance of the FFBPN for the prediction of IUGR and its subtypes.

The results are presented in table III and figure 3. Our results indicated that the FFBPN predicted the development of IUGR during pregnancy with a Se of 94.7%, Sp of 97.7%, and an FPR of 2%. The value of the area under the curve for this neural network was 0.978 (figure 3).

On the other hand, when stratified for the prediction of IUGR subtypes, the FFBPN achieved lower predictive performance. Also, the sensitivity analysis revealed that the FFBPN could better predict early IUGR, with a Se of 71.4%, Sp of 94%, and accuracy of 90.7%.

TABLE III.

The predictive performance of individual and combined tests for the prediction of ptb at 14 days

DISCUSSION

This pilot study evaluated the predictive performance of a FFBPN for the prediction of IUGR and its subtypes. Our results indicated that this type of neural network was good in discriminating those patients who would later develop intrauterine growth restriction. On the other hand, when faced with the prediction of IUGR subtypes, its discriminatory and predictive power were lower, but achieved overall good predictive performance for both early IUGR (accuracy of 92.6%), and late IUGR (accuracy of 90.7%).

Our results are comparable to those reported in previous literature. A recent retrospective study by Vicoveanu *et al.*, included 466 cases with thrombophilia, and used a FFPBN for the prediction of SGA newborns (18). Their results indicated a good predictive performance for the prediction of this disease, with an AUC value of 0.95, a true positive rate of 86.7%, and a false discovery rate of 10.5%. The overall accuracy of that model was 90%.

Moreover, Rescinito *et al.* performed a comprehensive systematic review and meta-analysis, encompassing a total of 20 studies, which investigated the utilization of artificial intelligence and machine learning models in the prediction of IUGR (19). The findings of this analysis revealed that the employed techniques exhibited a favorable diagnostic performance, with a Se of 0.84 (95% confidence interval [CI] 0.80-0.88), a Sp of 0.87 (95% CI 0.83-0.90), a positive predictive value of 0.78 (95% CI 0.68-0.86), and a negative predictive value of 0.91 (95% CI 0.86-0.94).

Although literature data is scarce regarding the use of this specific neural network for the prediction of IUGR, other studies have demonstrated overall good performance for other types of neural networks. For example, in a retrospective case-control study, Huang *et al.*, developed an artificial neural network, based on maternal peripheral blood parameters, that had an overall good predictive value for the occurrence of preeclampsia associated with IUGR (accuracy of 84.3%,Se- 97.7%, and Sp- 78%), as well as for the detection of severe IUGR (accuracy of 81.9%,Se- 97.2%, and Sp- 51%) (20).

Our study also confirmed the association between maternal risk factors such as smoking, autoimmune disorders and previous history of adverse obstetrical outcomes, and the occurrence of IUGR (21). Moreover, it outlined the significant differences regarding the serum levels of PlGF and PP-13 between the IUGR group and control, supporting the deficient angiogenesis theory in the development of this disorder (22).

This study has several limitations: small cohort of patients and the limited number of parameters included. On the other hand, this pilot study evaluated the predictive performance of a FFBPN in a prospective setting. Further studies, on larger cohorts of patients, could determine the cost-effectiveness of this type of FFBPN for the prediction of IUGR.

CONCLUSIONS

Neural networks are important tools for the prediction and stratification of various disorders, including IUGR.

It is important to provide a combined screening that included clinical, biochemical and ultrasound markers throughout pregnancy because later IUGR could be difficult to predict, especially from the first trimester.

Both PlGF and PP-13 could serve as important first trimester serum biomarkers for the prediction of ischemic placental disease, along with specific maternal and fetal risk factors.

CONFLICT OF INTEREST

The authors declare no conflict of interest.

THE AWARENESS OF MEDICAL WORKERS ON THE ARTIFICIAL INTELLIGENCE-BASED SOLUTIONS USED IN GASTROENTEROLOGY: AN EXPLORATORY SURVEY (Abstract): Recently, significant changes regarding the approaches in several areas of daily life, healthcare, and research are emerging due to technological advance. The benefits of using artificial intelligence (AI) in medical care are suggestive. However, the opinion of the users could suggest several potential limitations. We **aimed** to evaluate the trends in understanding and using the AI-based solutions available in Medicine. **Materials and methods:** An online survey was designed and distributed to the members of the local academic and healthcare community regarding their perception on the AI-based applications used in their area of expertise. Furthermore, several items aimed to evaluate the perception of the potential users on the perceived advantages and weaknesses of AI-based applications in healthcare and medical research. **Results:** One hundred and fifteen medical workers were recruited for this study, of mean age 41 ± 10.07 years, and of whom 56.5 % were women. The majority of the responses demonstrated general understanding of AI-based applications in daily life and in medical act. As emphasized by several participants, some of the limitations of AI use in healthcare could arise based on AI-based solutions. Despite this, AI-based resources could offer high performance solutions to medical care and research consequent to technological progress. However, one of the most important drawbacks of AI-based solutions used in medical care could be related to the empathy involved in patient management. **Conclusions:** Further studies regarding the possible means to improve algorithm-based decision-making processes could be addressed to minimize AI-based solutions in medical care. **Keywords:** ARTIFICIAL INTELLIGENCE, MEDICAL CARE, AWARENESS, PERCEPTION, GASTRO-ENTEROLOGY.

Artificial intelligence (AI) is currently known as the most advanced technical field in data analysis and research, as the novel algorithms closely resemble human intelligence through high-performance computer simulations (1). The concept of AI dates back to the mid-90s when it was first proposed by Alan Turing (2) and technically applied by John McCarthy throughout the Dartmouth Summer Research Project (3). The latter forecast the integration of AI in medical care, as the Turing test results were groundbreaking (associating the complexity of AI with the human brain) (4, 5). However, despite the initial excitement, the practical applications only recently materialized and led to the third scientific and technological revolution prior to unlimited data storage and instantaneous long-distance communication (6-8). While there are studies that point to some limitations (for example, unwanted effects on human cognition, as discussed by Firth *et al.* (9), AI technology was quickly introduced into different domains in daily life as well as in different professions, such as healthcare and medical practice, with promising applicability (10). In this context, AI-based solutions provided significant improvements in medical services, as reflected by high-resolution for the interpretation of images, prompt data processing, workflow enhancement, and lessening errors (11). Moreover, some opinions acknowledge the utility of AI in improving the efficiency of several activities that are currently affected by limitations, such as information acquisition (12).

Besides the algorithms behind AI and its three core processes (Machine learning - ML, Deep learning - DL, and Artificial neural network - ANN) which transpose into novel solutions for the most complex challenges, controversies also arise. One pivotal part is the scarce transparency of the AI algorithms, notably the black box (13), and probable inaccuracies in disease diagnosis and treatment by eroding the patient-doctor relationship (14). AI could offer the achievement of personalized medicine and precision public health through its virtual (ML/DL) and the branches that offer user interfaces (carebots) (15,16), but not without raising, as anticipated, numerous ethical, professional, and technical questions. Considering the skepticism and divergent viewpoints on AI from medical students, physicians, and individuals, opinion surveys may help understand their overall perception.

Thus, we aimed to evaluate the trends in understanding and use of AI-based solutions available in medicine and healthcare. We also wanted to see whether if the lack of awareness, and mistrust of the users could be possible sources of controversy.

MATERIALS AND METHODS

Study design

A survey based on previously published studies from the UK (17, 18) and the US (19) via the Delphi modified method (17, 20, 21) was designed and disseminated among the medical workers from the Institute of Gastroenterology and Hepatology from the "St. Spiridon" County Emergency Clinical Hospital, Iasi, Romania, and the 42nd National Congress of Gastroenterology, Hepatology, and Digestive Endoscopy held June 7-10, 2023, in Iasi, Romania. Based on the previously reported data regarding similar outcomes, the survey was structured in four sections (17-19, 22, 23): (1) demographic and professional data; (2) the understanding of general and daily life artificial intelligence; (3) the understanding of medi-

cal care AI-based solutions and the willingness to use, if available; and (4) the human versus machine controversy. The inclusion criteria were: (1) Romanian medical doctors; (2) in Gastroenterology and Hepatology field of expertise; and (3) those who were admitted to the residency program or had already completed their training. The exclusion criteria consisted in: (1) medical workers that did not undergo residency programs; (2) medical studies; (3) currently not involved in medical care; or (4) medical workers whose expertise was not compatible with the Gastroenterology field.

Data analysis

All the data from the online surveying tool was collected in Excel format via the export option. *Version 26.0 of SPSS* (IBM SPSS Inc., Chicago, IL, USA) was used to statistically analyze the data. All the variables expressing categorical data were presented as percentages, while numerical variables were reported as mean and standard deviation (SD). Odds ratio, Wald test, and Fisher exact probability test were used to determine the influence of the demographic/professional variables on the binary answer items.

Ethical considerations

The survey was designed to be appropriate for online distribution via a free survey platform and was approved by the Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy (No. 301/4 May 2023). All the participants agreed with written informed consent and were recruited voluntarily, anonymously, and free of charge. Efforts were made not to collect personal data.

RESULTS

Demographic and professional characteristics

One hundred and fifteen medical care workers positively responded to the recruitment announcement via online notification. The description of the recruited participants in terms of demographic and professional characteristics is presented in tab. I. The sex distribution of the study group was 43.4 % males and 56.5 % females, while the mean age was 41 ± 10.07 years. The age interval of 30 - 39 years was predominant (47.82 %). All the participants came from the urban area. Finally, concerning the profession, about half of them (52.17 %) were primary care physicians.

TABLE I.

Demographic and professional characteristics of the population included in the study

Characteristics		Study group (N=115) n (%)
Gender	Male	55 (43.4)
	Female	65 (56.5)
Age	< 30	10 (8.69)
	30-39	55 (47.82)
	40-49	20 (17.39)
	> 49	20 (17.39)
	Total (years, mean ± SD)	41 ± 10.07
Medical experience	Resident doctor	15 (13.04)
	Medical specialist	40 (34.78)
	Primary care physician	60 (52.17)

Participants perceptions on artificial intelligence and everyday use

The second section of the survey focused on evaluating the general perceptions of the participants toward AI and their preferences to use basic and general AI-based applications, as they are available in daily life technology. The definitions offered by the participants for AI ranged between "algorithms" and "technology" (fig. 1). While 69.56 % of the participants use AI-based applications in their everyday lives, most of the participants generally enumerated chatbots (20.18 %), medical apps and AI-based scores (20.18 %), statistical tools (7.89 %), voice commands and recognition (11.40 %), and other multimedia apps and platforms (10.53 %) as the main AI-based solutions they encountered.

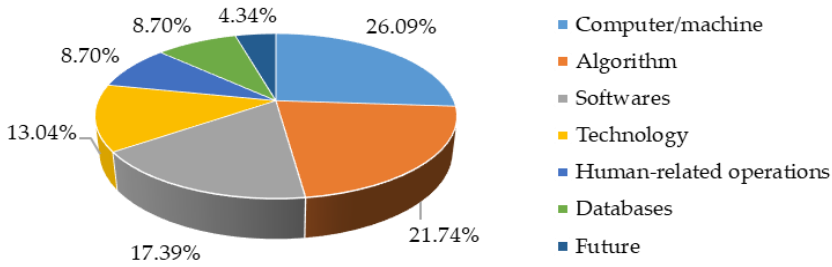

Fig. 1. Participants' preferences to use basic and general AI-based applications

Regarding the limitations of AI technology, 73.91 % of the respondents agreed that AI-based applications equally imply both advantages and disadvantages. While more than half of the respondents (52.17 %) do not consider that AI-based solutions could be the subject of serious security breach, emotional and social issues (26.09 %), addiction (17.39 %), and predisposition to errors (16.52 %) were also mentioned as limitations (fig. 2). Furthermore, almost 70% of the participants stated that AI could possibly replace humans in certain tasks at some point in the future.

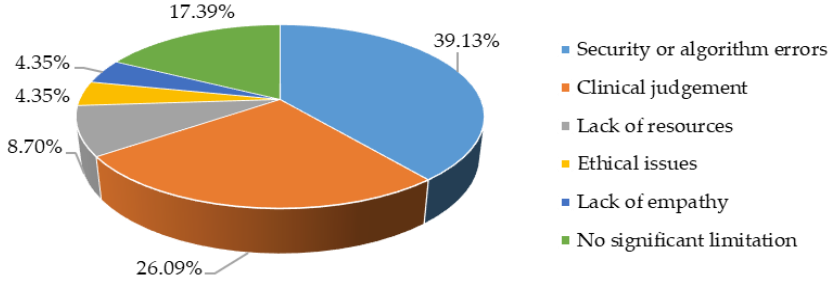

Fig. 2. Limitations of AI-based applications that are available for gastroenterology practice

Moreover, our results showed that neither age (OR=1.0085, 95% CI=(0.9661, 1.0527), p=0.7), nor the sex (OR=1.0370, 95% CI=(0.4650, 2.3127), p=0.92), did

significantly contribute to a segregation of responses regarding the idea of human being replaced by AI in certain tasks. On the other hand, all the medical residents and most of the primary care physicians (83.33 %) stated that AI could possibly replace humans in certain tasks at some point in the future. By contrast, only 37.5 % of the medical specialist doctors had the same opinion, this being a significant difference (χ^2=31.36, p < 0.001, in Fisher exact probability test).

The understanding and use of AI-based solutions in gastroenterology

The third section of the survey aimed to evaluate the awareness of the participants on the AI-based solutions available for clinical practice in Gastroenterology. Not necessarily connected to the current field of practice, the most of the respondents (86.95 %) stated that Telemedicine would be a valuable tool in primary care. When we applied data stratification tests, we found that age (OR=0.9427, 95% CI=(0.8951, 0.9928), p=0.025) was significantly correlated as contributor to this opinion. Moreover, we found that men were less likely to report a positive response, as compared to women (OR=0.33, 95% CI=(0.1060, 1.0482), p=0.05). The analysis of the data showed that the medical experience of the respondents did not pose a significant difference in responses on the value of Telemedicine, as we found that all the medical residents, 12.5 % of the medical specialist doctors, and 21.27 % of the primary care physicians gave a positive answer at this question (χ^2=2.95, p=0.22, in Fisher exact probability test).

More than half of the participants (52.17 %) considered that AI-based applications in Gastroenterology equally imply both advantages and disadvantages. However, most of the respondents pointed out that the limited resources (finances, time, and trainers) and AI-specialized personnel could be possible sources of reduced use of AI-based applications in their field of activity. Also, almost half of the respondents stated that they had not previously attended scientific events (43.47 %) or were not planning to register for training courses (56.52 %). In addition, the participants highlighted that the lack of clinical judgment and empathy, security or algorithm errors, the expense of resources, and ethical issues could raise some concerns regarding the use of various applications based on AI that are available for Gastroenterology practice (fig. 3).

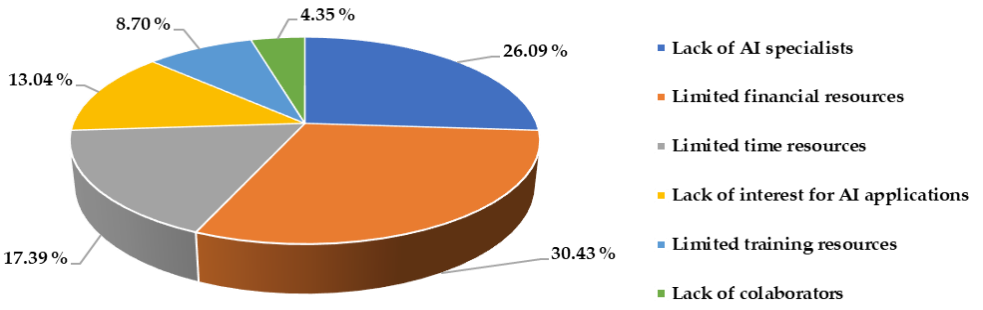

Fig. 3. Limitations of AI-based applications that are available for gastroenterology practice

Nevertheless, 86.95 % of the participants suggested that AI-based applications used in Gastroenterology could lead to some discordance between algorithmic response and medical decision. Despite this, 91.3 % of the medical doctors that were interviewed are not concerned about the possibility of being replaced by AI in their field. Our results showed that the age (OR=1.1798, 95% CI=(1.0393, 1.3394), p=0.01) of the participants significantly contributed to the stratification of the results in terms of the possibility of being replaced by AI in the field. Moreover, we observed that men are more likely to report this possibility, as compared to women, but not in a significant manner (OR=1.3333, 95% CI=(0.3639, 4.8848), p > 0.05). Also, we observed that neither medical residents, nor primary care physicians positively responded to this item (Fisher exact probability test not performed). In this context, most of the participants agreed that AI-based applications could be useful in diagnosis and treatment. However, the need for human validation was repeatedly mentioned in the situation of receiving AI-based suggestions on differential diagnosis, paraclinical investigations, and drug interactions. Moreover, some of the participants highlighted that these suggestions would not be as useful as predicted if a dichotomous response is present when the medical decision implies temporization or prioritization rather than a choice between action and non-action.

DISCUSSION

Healthcare is currently one of the most important branches in our society, and thus continuous development to improve diagnosis and treatment is needed. Together with the development of AI technology in the last decade, many solutions also address the medical care. In this way, as Gastroenterology also vastly benefited from AI-based solutions in paraclinical investigation, diagnosis, and treatment, we aimed to evaluate the perception of gastroenterologists regarding the extension of AI-based solutions used in their field. The results of our survey showed that, in contrast to previous similar studies, the participants recently gained more knowledge regarding the general understanding of AI (as seen in daily use) and in their area of expertise. However, this perception improvement did not significantly change the opinion of the participants on the advantages and disadvantages of daily life and professional AI-based solutions, findings that were consistent with previous similar studies (22, 24, 25).

The IMDRF SaMD Working Group (26) initially described medical devices as tools to be used in prevention, diagnosis, and disease management (ranging from treatment monitoring to symptoms alleviation or life support). The implications of AI-based software in these healthcare endeavors are meant to bring important improvements in the speed, precision, and accuracy of the medical act. However, the majority of the participants agreed that human validation is needed when AI-based applications are used in medical care and that the medical decisions should only be attributed to the human involved in the medical act, regardless of the assistance of the AI. In accordance with this, a recent study that evaluated the opinion of the American public on triage or discharge decisions showed a clear preference for human medical professionals over an AI-based algorithm (27). With regards to the possibility of being replaced by AI in their domain, almost all the participants in our study expressed no concerns about this aspect, as they clearly pointed out that the lack

of empathy of the AI-based applications could possibly prevent this. Goldhahn *et al.* (28) described the patient inputs during the medical act as a variety of emotions, values, personal preferences, and non-verbal communication that could hardly be substituted by technology. In this context, recent efforts were made to improve AI-based technology used in healthcare to recognize and respond to the facial emotions of the users, especially in carebots and online platforms/apps for mental therapy (29). However, the most difficult challenge for AI-based solutions in healthcare is their implementation in daily clinical practice, instead of determining whether the technologies will be capable enough to prove their effectiveness (30-32). In the present study, most of the respondents noted that AI-based technology could be helpful in diagnosis and treatment, leading to significant improvements in the patient's life. In addition, a recent review suggested that by adding AI technology to the healthcare system, the expertise of medical personnel could be complemented and enhanced, thus contributing to improved service quality, patient outcomes, and system performance (33).

Lately, due to the fast progress of technology, many AI-based resources have successfully been implemented in Gastroenterology. For an instance, high-performance recognition software was technologically customized for real-time endoscopy, along with high-quality graphical interfaces (34,35). Despite the fact that these tools proved their utility, some arguments are brought by the manifestation of obsolete behavior in clinicians when AI-based technology advances in performance and quality. In this context, the refusal of healthcare workers to use AI-based resources could be explained due to inflexibility or a lack of AI specialists, as seen in our study and also suggested by Quinn *et al.* (36) and Lambert *et al.* (37). Moreover, we identified that the lack of significant resources, such as financial support or time, could contribute to the limitation of AI-based solutions use during the medical act.

Regarding the possible errors that could occur during implementation and use, most of the participants in our study highlighted that AI-based solutions could be the source of some security issues. This limitation was documented by Pedro et al (38) and solutions such as permanent evaluation and update of the software by technical engineers, as well as standard, logistic, and ethical guidelines for AI-based solution implementation in healthcare were proposed.

Some of the main limitations of the present study address the reduced number of participants, the complexity of the survey, and the focus on just one medical specialty. However, we are currently considering to further extend the number and the medical field of the recruited participants. Concussive with this, we aim to improve the survey to include more aspects of AI-based solution awareness, as the current form of the survey was an initial and a less complex design. AI-based solutions are of great variety throughout the medical fields, thus the survey could also evaluate some field-specific aspects. Consequently, this preliminary data could only provide more information regarding the awareness of medical workers involved in Gastroenterology and Hepatology area of expertise.

CONCLUSIONS

This study reflected the awareness of the recruited medical workers regarding the potential of the use of AI-based solutions as helpful tools in the medical field, offer-

ing substantial advantages in both diagnosing patients' conditions and resolving their issues through the use of pre-established algorithms. However, AI-based solutions could need substantial resources, such as finances, time, and specialists, to provide the expected results. Nevertheless, AI-based solutions could be seen as valuable assets that could bring important improvements in the speed, precision, and accuracy of the medical act. However, AI-based solutions could require solid validation and thorough training of the users.

CRIP-1 OVEREXPRESSION - PROGNOSTIC FACTOR IN CHILDREN'S OSTEOSARCOMA? (Abstract): Predicting the clinical evolution of patients with osteosarcoma is an essential condition for personalized treatment. In researching new and reliable biomarkers we identified CRIP-1 (Cysteine-Rich Intestinal Protein 1). Its *overexpression* has been documented to have a significant prognostic impact on gastric and colorectal cancer. Therefore, we aimed to investigate the *overexpression* of CRIP-1 in pediatric osteosarcoma and assess its potential as a prognostic biomarker. **Materials and methods:** We analyzed 65 samples from patients diagnosed with osteosarcoma at "Sf. Maria" Emergency Clinical Hospital for Children from Iasi, between 2017 and 2021. Two staining kits were used: Mouse and Rabbit Specific HRP/DAB (ABC) Detection IHC Kit from Abcam and Novolink Poly HRP Kit. **Results**: CRIP-1 was over expressed in 92.6% of the cases. The lower the degree of differentiation, the less CRIP-1 is over expressed and the more frequently it is found in the nucleus. **Conclusions:** Could this mean that CRIP-1 overexpression is associated with a better prognosis? The study highlights the clinical implications of CRIP-1 in osteosarcoma, emphasizing its importance for prognosis, and personalized treatment strategies. However, it calls for further investigation into CRIP-1 role in cancer biology (molecular pathways and interactions with other prognostic factors). **Keywords:** OSTEOSARCOMA, CRIP-1 OVEREXPESSION, CANCER, PROGNOSIS.

INTRODUCTION

Osteosarcoma is the most common malignant bone tumor in children and adolescents, characterized by aggressive growth (1, 2). One of the significant challenges in managing osteosarcoma is the high rate of metastasis observed at the time of diagnosis (3). This underscores the critical need for early detection and the identification of biomarkers that can predict therapeutic outcomes and disease progression.

Although advancements in treatment protocols have increased the 5-year survival rate to 50–70% (4, 5), a considerable number of patients still face recurrent or refractory metastatic disease with limited therapeutic options (6). To address this, there is an urgent need to identify reliable biomarkers that can forecast the prognosis of osteosarcoma patients, ultimately facili-

tating personalized therapy (7).

Identifying tumor markers and elucidating their interrelationships could pave the way for targeted and individualized therapies, thereby improving the survival rates and quality of life for cancer patients.

Studying the osteosarcoma microenvironment, both *in vitro* and *in vivo*, can enhance our understanding of the tumor's evolutionary behavior. Combining the expression profiles of specific biomarkers with responses to monotherapy or combined therapies in pediatric osteosarcoma could explain various clinical and evolutionary characteristics, leading to improved clinical and therapeutic management (8).

Cysteine-Rich Intestinal Protein 1 (CRIP-1) is a member of the LIM/ double zinc-finger protein family, involved in regulating cellular processes such as growth, differentiation, and apoptosis (9, 10, 11). CRIP was first identified as a developmentally regulated intestinal gene and has since been found in a variety of different tissues and cells (11). CRIP-1 has emerged as a potential biomarker of interest in various cancers. Studies have indicated that CRIP-1 expression is altered in several malignancies, including breast, colorectal, gastric, cervical, ovarian, thyroid, pancreatic, and prostatic cancers, suggesting its role in tumor genesis and cancer progression (9, 10, 12, 13, 14, 15, 16, 17, 18, 19, 20).

However, the role of CRIP-1 in osteosarcoma, particularly in the pediatric population, remains underexplored. Given its involvement in other cancer types, CRIP-1 may serve as a prognostic factor in osteosarcoma, potentially influencing tumor behavior and patient outcomes. Investigating CRIP-1 expression in osteosarcoma could provide new insights into the disease's molecular mechanisms and identify targets for novel therapeutic interventions.

This study aims to evaluate CRIP-1 overexpression as a prognostic biomarker in pediatric osteosarcoma. By analyzing CRIP-1 expression levels in osteosarcoma tissue samples and correlating these levels with clinical outcomes and pathological features, we seek to determine its potential utility in predicting disease progression and guiding treatment decisions. Our findings could contribute to the development of more effective, individualized treatment strategies for young osteosarcoma patients, ultimately improving survival rates and quality of life.

MATERIALS AND METHODS

A total of 65 samples from patients diagnosed with osteosarcoma at “Sf. Maria” Emergency Clinical Hospital for Children from Iasi, between 2017 and 2021, were analyzed. The tissue samples obtained from the cases in this study were processed using a standardized protocol. They were fixed in 10% buffered formalin, decalcified with EDTA, and embedded in paraffin. Sections of 5/4 µm were then prepared and transferred to electrostatically charged slides for subsequent immunohistochemistry analysis.

Two staining kits were used: Novolink Poly HRP and Mouse and Rabbit Specific HRP/DAB (ABC) Detection IHC Kit and CRIP-1 antibody from Abcam.

Initially, we used the Novolink Poly HRP kit, but it proved incompatible with the antibodies. Consequently, we switched to the Abcam Mouse and Rabbit Specific HRP/DAB (ABC) Detection IHC kit, which yielded positive results. Each staining process included both positive and negative controls to ensure that the staining

system functioned correctly, the positive and negative staining procedures were specific, and the specific protocol was properly followed.

CRIP-1 shows cytoplasmic and nuclear staining. The expression of CRIP-1 was assessed using the scores reported by Yu *et al* (21). The H-scores were calculated by determining the intensity of the staining and the percentage of the staining region with that intensity. Only stained cancerous cells were examined. The samples were divided into four different categories based on the intensity of nuclear or cytoplasmic staining: none = negative (0), weak (1), medium (2), and strong (3). The indexed total was calculated by multiplying the intensity grade by the percentage of stained region.

Specificity and sensitivity points can help maximize the positive rate. A score was assigned based on the number of stained cells and ranges from 0-4% to 80–100%. The score was judged poor from 1 to 5 (1 = 0-4%; 2 = 5-19%; 3 = 20-39%; 4 = 40-59%; 5 = 60-79%) and high from 6 (= 80-100%) to 18. We have multiplied 0 - 18.

The research was approved by the Ethics Committee of the "Sf. Maria" Emergency Clinical Hospital for Children from Iasi

RESULTS

In our research, CRIP-1 expression was assessed in 65 osteosarcoma tissue samples that met histopathological criteria. Patient observation sheets provided clinical and pathological information such as age, sex, tumor size, tumor grading, and the presence or absence of metastases. In the majority of cases, a diagnostic bone biopsy was the primary surgical procedure. By comparing the anatomopathological reports to the clinical data and immunohistochemistry findings, we discovered that the majority of patients were male, with ages ranging from 8 to 19 years; the highest incidence occurred at age 16. The most prevalent tumor location was the femur, namely the distal femur. The most common histological diagnosis was osteoblastic osteosarcoma (figs. 1, 2), followed by chondroblastic osteosarcoma, pleomorphic osteosarcoma, and clear-cell osteosarcoma.

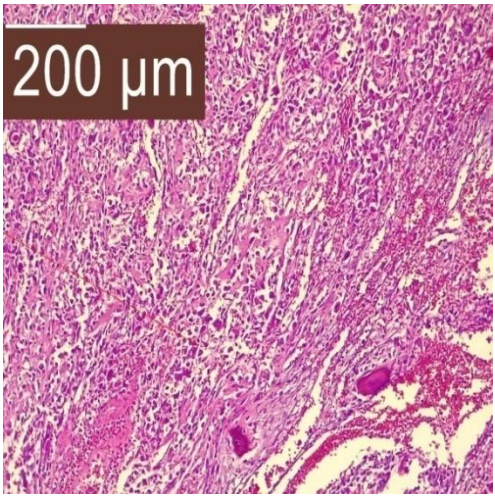

Fig. 1. Osteobalstic osteosarcoma, staining HEx10

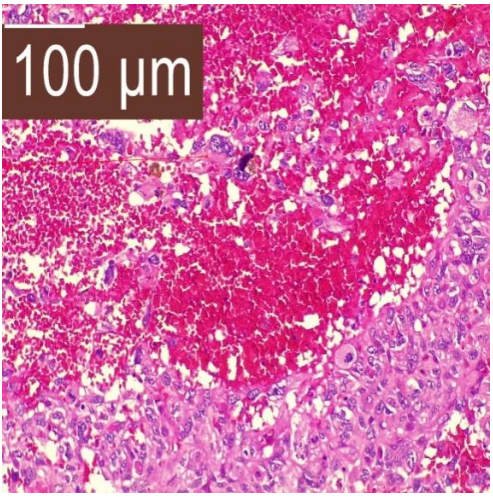

Fig. 2. Osteoblastic osteosarcoma, staining HEx2

From the perspective of tumor grading, our findings indicated that over 70% of the osteosarcoma cases were classified as high-grade, characterized by poorly differentiated and undifferentiated tumors (tab. I).

Metastasis was identified in two cases: one with lung metastasis and the other with skin metastasis.

TABLE I.
Anatomopathological characteristics of the cases

Variables	No. of cases	%
Tumor grade		
Grade 1 - well differentiated	8	12.3
Grade 2 - moderate differentiated	11	16.9
Grade 3 - poorly differentiated	38	58.5
Grade 4 - undifferentiated	8	12.3
H-score (CRIP-1% of nuclear/ cytoplasmic staining)		
3 = between 20-39	1	1.5
4 = between 40-59	2	3.1
5 = between 60-79	25	38.5
6 = between 80-100	37	56.9
CRIP-1 intensity		
negative	3	4.6
weak	19	29.2
medium	29	44.6
strong	14	21.6

Regarding CRIP-1 antibody staining, one case could not be assessed due to a technical defect. However, in the remaining cases, cytoplasmic and/or nuclear staining was observed, with over 60% of tumor cells showing positive staining (scoring 5 and 6) (tab. I).

Medium CRIP-1 staining was observed in 88.88% of osteoblastic osteosarcomas (figs. 3, 4, 5) and 85.71% of chondroblastic osteosarcomas (fig. 6). In pleomorphic osteosarcomas, 50% of cases exhibited strong CRIP-1 staining.

In the majority of examined cases, the staining intensity was medium and localized either cytoplasmic, nuclear, or both (Table I). Strong staining was noted in all cases of well-differentiated osteosarcoma. Among poorly differentiated osteosarcoma, 50% demonstrated intense staining. Also, high-score nuclear staining was identified in 50% of the undifferentiated osteosarcoma forms.

CRIP-1 was over expressed in 92.59% of cases. In the 2 metastatic blocks, staining was absent in the case with frontal skin metastasis and weak in the case with pulmonary metastasis, despite the overexpression (strong staining intensity) observed in the primary tumor. A correlation between histopathological type and staining intensity for CRIP-1 could not be established.

The lower the degree of differentiation, the less CRIP-1 is over expressed and the more frequently it is found in the nucleus.

DISCUSSION

Even though several studies have linked CRIP-1 expression to a poor prognosis in colorectal, breast, gastric, prostate, cervical, ovarian, thyroid, pancreatic, and endometrial cancer (10, 12, 13, 14, 15, 16, 17, 18, 19, 20, 25), there are very few published papers on the role of CRIP-1 in osteosarcoma (9, 22).

The data reported on the topic revealed contradictory results regarding the impact of CRIP-1 on osteosarcoma. A study published in 2011 demonstrating that CRIP-1 expression is strongly associated with a

favorable outcome and as significant negative predictors of systemic spread in osteosarcoma (9). A more recent work reported that overexpression of CRIP-1 was associated with a poor survival of osteosarcoma patients (22). Probably CRIP-1 has oncogenic and tumor suppressor properties specific to the tumor type, which require further clarification of the pathogenesis.

Our study aimed to investigate the expression of CRIP-1 in osteosarcoma tissue samples and its correlation with various clinical and pathological features, exploring the potential of CRIP-1 as a prognostic biomarker. The results revealed significant patterns in the demographic distribution, tumor characteristics, and CRIP-1 staining intensity, providing insights that contribute to the existing body of knowledge on osteosarcoma.

The demographic data showed that the majority of osteosarcoma patients were male, with ages ranging from 8 to 19 years, and the highest incidence occurring at age 16. These findings are consistent with previous research, which indicates a higher prevalence of osteosarcoma in males during adolescence-a period marked by rapid bone growth (22, 23). The predominant tumor location was the distal femur, aligning with literature that highlights the long bones around the knee as common sites for osteosarcoma (9, 22).

Osteoblastic osteosarcoma was the most frequent histological subtype, followed by chondroblastic, pleomorphic, and clear-cell osteosarcomas. This distribution mirrors established patterns, where osteoblastic osteosarcoma is commonly the most diagnosed subtype (22, 24). In the current research, over 70% of cases were classified as high-grade, characterized by poorly differentiated and undifferentiated tumors, which are known to be associated with aggressive disease and poorer prognosis (23). The presence of metastasis in two cases further underscores the aggressive nature of high-grade osteosarcomas.

Our findings on CRIP-1 expression revealed that over 60% of tumor cells exhibited positive staining for CRIP-1, with varying intensities and localization patterns, results that were in line with the literature (9). Baumhoer and collaborators reported 45% of cases with CRIP-1 expression (9). In the current research, CRIP-1 was overexpressed in 92.59% of cases, predominantly showing medium staining intensity. Notably, strong CRIP-1 staining was observed in all cases of well-differentiated osteosarcoma, and high-score nuclear staining was identified in 50% of undifferentiated osteosarcomas. This suggests that CRIP-1 expression may be associated with tumor differentiation status, where better-differentiated tumors show stronger CRIP-1 expression.

Interestingly, the correlation between CRIP-1 staining and metastatic potential revealed that metastatic tumors exhibited weaker CRIP-1 staining compared to their primary counterparts. Specifically, the case with pulmonary metastasis showed weak staining, and no staining was observed in the case with frontal skin metastasis. This disparity suggests that CRIP-1 expression might be reduced in metastatic lesions, indicating a possible role of CRIP-1 in the primary tumor environment but not in metastatic sites.

The study is limited by the small sample size and the retrospective nature of data collection, which may affect the general applicability of the findings. Additionally, technical issues in assessing one sample highlight the need for robust methodologies

in future studies. Prospective studies with larger cohorts are necessary to validate our findings and further elucidate the role of CRIP-1 in osteosarcoma pathogenesis. Functional studies exploring the molecular mechanisms of CRIP-1 could provide deeper insights into its role as a potential biomarker and therapeutic target.

CONCLUSIONS

Our study offers significant insights into the demographic and clinical characteristics of osteosarcoma, with a particular focus on the expression of CRIP-1. The data indicate that CRIP-1 is markedly overexpressed in osteosarcoma tissues and its expression appears to be correlated with the differentiation status of the tumor. Specifically, well-differentiated tumors tend to exhibit stronger CRIP-1 staining. Furthermore, the observed disparity in CRIP-1 expression between primary and metastatic tumors suggests that CRIP-1 may play a distinct role in the primary tumor environment compared to metastatic sites. These findings highlight the potential of CRIP-1 as a biomarker for osteosarcoma and suggest avenues for future research into its mechanistic roles and therapeutic potential. Prospective studies with larger patient cohorts and functional analyses of CRIP-1 are essential to validate these observations and to fully elucidate the implications of CRIP-1 expression in osteosarcoma. Understanding the role of CRIP-1 could lead to the development of novel diagnostic and therapeutic strategies, ultimately improving clinical outcomes for patients with osteosarcoma. We propose to expand this study by investigating the correlation between CRIP-1 overexpression and survival rate in patients with osteosarcoma.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest in their scientific research.

TESTICULAR TUMORS IN PEDIATRIC POPULATION: SINGLE CENTER EXPERIENCE (Abstract): Our study **aims** to provide valuable contributions to the understanding and management of this rare condition, with a particular focus on our single-center experience and analysis of cases in light of limited worldwide reports. **Materials and methods:** This study analyzed 18 patients between 2003 and 2023. We categorized patients into two age groups: prepubertal (ages 0-11 yrs.) and postpubertal (ages 12- 18 yrs.), based on the typical onset of puberty in males, in order to compare distinct tumor characteristics. We assessed clinical data, staging imaging, pre-operative serum tumor marker values, surgical approaches, chemotherapy protocols, and clinical outcomes. **Results:** There was no significant difference in the prevalence of the different types of clinical presentations between groups. The overall survival (OS) rate was 94.4%, while the progression free survival (PFS) was 77.8%. The postpubertal age group had a significantly lower PFS period compared to patients in the prepubertal age group. **Conclusions:** This research highlights the importance of precisely performing physical, imaging, and biological tests for the early detection of testicular cancer. It emphasizes the significance of ongoing research and collaborative efforts to enhance testicular cancer management. **Keywords:** TESTICULAR, TUMORS, PREPUBERTAL, POSTPUBERTAL, CHILDREN, ADOLESCENTS.

Testicular tumors (TT) are uncommon across the pediatric population, with an annual incidence of between 1.6 and 2 cases per 100,000 children (1, 2). Based on age, TT in boys exhibits a bimodal distribution, occurring between 2 and 4 years or during infancy (prepubertal group) and after 12 years (postpubertal group) (3). Clinical considerations during these age periods are essential for choosing appropriate and distinct treatment strategies. Given the scarcity of cases and the limited literature available globally on this topic, our goals are to underline the clinical, pathological, and outcome data from single-center cases to enhance understanding and inform future clinical practice.

MATERIALS AND METHODS

This study analyzed only the children with TT who were admitted to our institution between January 2003 and January 2023. We retrospectively selected patients using the ICD-10 coding system and re-

viewed medical chart records for epidemiological and clinical data, staging imaging, pre-operative serum tumor marker levels (STM), surgical procedures, medical oncology therapy(s), clinical outcomes, and the histological subtype. We categorized patients into two age groups: prepubertal (0- 11 years) and postpubertal (12- 18 years), based on the typical onset of puberty in males, approximately at 12 years of age.

Data from the study were analyzed using IBM *SPSS Statistics versions 20 & 25* and illustrated using Microsoft Office Excel/Word 2013. Quantitative variables were tested for normal distribution using the Shapiro-Wilk Test and expressed as averages with standard deviations or medians with interquartile ranges. Kaplan-Meier curves were used to illustrate and calculate overall survival time (OS) and progression-free survival time (PFS) in the analyzed groups. Tarone-Ware tests were used to compare OS and PFS between age groups.

RESULTS

We have identified 18 children with TT, 10 cases in the prepubertal group and 8 cases in the postpubertal group (tab. I). Detailed family histories were limited in the study. One 7-year-old patient had a history of multicystic renal dysplasia. Incidental palpable testicular mass was most common in the 12-18 age group (8/8), but there was no significant difference compared to the 0-11 age group (9/10) (p-value = 0.387). In our study, right-side tumors were more common (10/18), and no patients had bilateral tumors. Testicular pain was more prevalent in postpubertal patients (5/8) compared with prepubertal patients (1/10). Only one child from the postpubertal cohort presented with respiratory distress syndrome because of pulmonary metastasis.

TABLE I.

Comparison of diagnostic age according to age groups

Age	Average ± SD	Median (IQR)	Mean rank
Prepubertal	1.46 ± 2.01	0.91 (0.64-1.25)	5.50
Postpubertal	15.87 ± 1.8	17 (15-17)	14.50

Ultrasound was performed on all symptomatic and diagnosed patients, and only 7 required additional imaging. Computed tomography (CT) was used in 5 out of 18 patients, while magnetic resonance imaging (MRI) of the abdomen and pelvis was used in 2 out of 18 cases. The decision to conduct additional imaging studies was made based on clinical judgment and specific indications. These indications primarily included symptoms suggestive of advanced disease or findings on initial ultrasound examinations warranting further evaluation for accurate staging and treatment planning. In our study cohort, only a subset of patients met these criteria and thus required additional imaging studies. CT scans were exclusively performed on post-pubertal patients (n = 5), and only two results revealed significant findings related to disease spread (p-value = 0.016).

Positron emission tomography (PET-CT) was performed on three postpubertal patients. In the first case, the patient follows the chemotherapy protocol with favorable clinical progress. We conducted imaging one year

after diagnosis, which revealed certain lung abnormalities on CT scans; subsequently, a PET-CT scan was performed, which identified a probability of secondary pulmonary dissemination and hypermetabolism at the mediastino-pulmonary and bilateral axillary levels. While complete exclusion of dissemination was not possible, suspicion of pulmonary and nodal metastasis was high, leading to the initiation of a second-line chemotherapy protocol. In the second case, the patient presented with metastases upon admission and underwent initial chemotherapy for six months; subsequently, a PET-CT was deemed necessary, revealing metabolically active tumor remnants. In the last case, it was performed two months after finishing chemotherapy regimens, prompted by the parents' insistence on obtaining this exam and no detectable malignant FDG-hyper captured lesions were observed.

Histologic subtypes included 7 (38.88%) mixed germ cell tumors (mixed GCTs), 4 (22.21%) immature teratomas, 3 (16.66%) Yolk Sac Tumors (YSTs), 2 (11.1%) PT-RMS, 1 (5.55%) embryonal carcinoma (EC), and 1 (5.55%) cystic dysplasia of the testis (tab. II). Even though PT-RMS is not a TC, we included these 2 patients in our study due to the paratesticular mass. Immunohistochemistry diagnostic procedures were performed on a limited sample, comprising three patients (16.67% of the cohort). These evaluations were specifically focused on 2 PT-RMS (11.1%) and, regarding non-GCNIS derived tumors, were exclusively performed on an 8-month-old patient diagnosed with mixed GCT.

TABLE II.

Patient distributions according to age and histologic subtypes

Tumor subtype	0 - 11 yrs.	12 - 18 yrs.	p-value
Germ cell tumors derived from germ cell neoplasia in situ			0.002
-Mixed Germ Cell Tumors	1	6	
-Nonseminomatous germ cell tumors: Embryonal carcinoma	-	1	
Germ cell tumors unrelated to germ cell neoplasia in situ			
-Teratoma, prepubertal type (immature)	4	-	
-Yolk sac tumor, prepubertal type	3		
Paratesticular tumors (PT-RMS)	1	1	
-Cystic dysplasia of testis (benign)	1	-	

STM values were available for all cases, and measurements were performed preoperatively (tab. III). Alpha-fetoprotein (AFP) levels (normal value <34.8 ng/mL) ranged from 39 ng/mL to 5321 ng/mL (median 2255 ng/mL) in malignant cases. Patients from the postpubertal group had human chorionic gonadotropin (hCG) levels (normal value <1.2 mIU/mL) ranging from 150 mIU/mL to 45654 mIU/mL in malignant cases. The highest hCG value was observed in the patient with mixed GCTTs who had metastases at the time of the presentation. hCG and lactate dehydrogenase (LDH) levels were within the normal range in the prepubertal group. Elevated levels of both AFP and hCG were observed in six postpubertal patients. Among them, five patients were diagnosed with mixed GCTs, while one patient had EC.

TABLE III.
STM distribution according to age groups and histological subtype

Age group (No)/ STM	5 - 11 yrs.	12 - 18 yrs.	p-value
AFP elevated	3	7	0.038
- histological subtype	YST- 2 IT- 1	Mixed GCTTs- 5 EC- 1 PT-RMS- 1	
- highest value (ng/mL)	1800	5321	
hCG elevated	-	6	0.036
- histological subtype	-	Mixed GCTTs- 5 EC- 1	
- highest value (mIU/mL)		45654	
LDH elevated	-	6	0.001
- histological type	-	Mixed GCTTs- 6	
- highest value (U/L)		1200	

All patients within the age range of 12 to 18 years underwent radical inguinal orchidectomy (RO). Testicular sparing surgery (TSS) was deemed appropriate for three patients in the prepubertal age group; Initially, in two patients, the strategy involved performing a total excision of the tumor while preserving the seemingly unaffected testicular parenchyma. However, after a few days, a RO was decided upon following the pathological examination, which revealed a mixed GCT/ YST. In the last case of TSS, a surgical procedure was performed through a trans scrotal approach. Additionally, the right testicle showed enlargement attributed to the presence of a multicystic, septated tumor that was composed of serous citrine fluid. A biopsy was performed on the cystic mass and the testicle, with an extemporaneous evaluation ruling out malignancy. A 1-year-old patient, previously diagnosed with YST and who underwent trans scrotal orchidectomy at another medical facility, presented to our department with a local recurrence in the left hemiscrotum. As a result, a second surgery was performed to remove the recurrent area.

In the prepubertal group, seven patients received platinum-based chemotherapy (CHT) protocol and the SIOP MMT 95.3 protocol was used for patient with PT-RMS. In the postpubertal group, six children underwent platinum base CHT protocol, and patient diagnosed with PT-RMS was initially treated with vincristine, dactinomycin, and cyclophosphamide (VAC Protocol), but due to metastasis spreading to the lungs and lymph nodes, a second regimen with temozolamide and irinotecan was required.

Among the study participants, metastatic spread was observed in two postpubertal cases at initial presentation in our institute. One patient with mixed GCT and another case involved a patient with EC. After initial diagnosis, subsequent metastasis developed in one prepubertal patient after 14 months, and in three patients from the postpubertal group at 8, 12, and 18 months, respectively. The most frequently affected sites were the lung and retroperitoneal lymph nodes, followed by the brain and bones.

To obtain details concerning survival and mortality, an official request was sent

to the National Register of Persons (No. 19315-2022) for the public disclosure of relevant data. Due to the low frequencies of deaths (1 case- 5.6%) and disease events (4 cases- 22.2%), medians with interquartile ranges could not be computed for the OS and PFS periods. As such, the overall survival rate was 94.4%, while the PFS was 77.8%. According to the Tarone-Ware tests, the PFS period was significantly different (**p= 0.047)**. Patients in the postpubertal age group had a significantly lower PFS period (mean = 14, 95% C.I.: 8.15- 19.84 months) in comparison to patients in the prepubertal age group (mean = 187.33, 95% C.I.: 147.29- 227.37 months) (fig. 1).

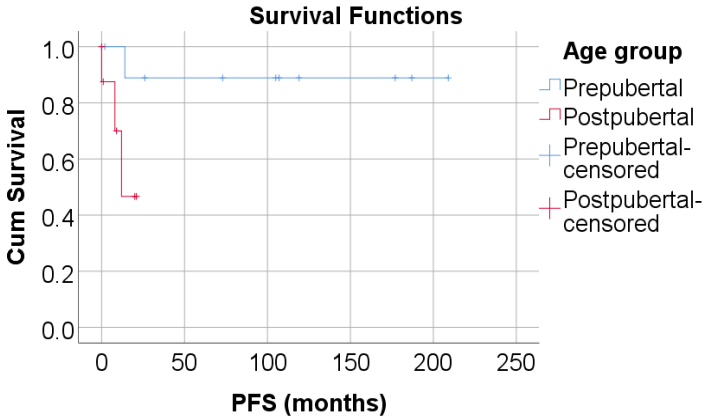

Fig. 1. Comparison of PFS period according to the age groups

DISCUSSION

In this article, we present our experience from a single center focusing on the pediatric population up to 18 years of age. Our hospital serves as a primary referral center for pediatric oncology in Eastern Romania, covering a significant region where the majority of pediatric tumors are treated. The risk of TC is 2-5 times higher in individuals with a history of cryptorchidism (the normal incidence is 1 in 400 men) (4). In contrast to documented risk factors, data on the risk associated with testicular microlithiasis (TM) are contradictory (5). In our study, none of the patients had a known history of cryptorchidism, and only one patient with cystic dysplasia of the testis had a personal history of multicystic renal dysplasia. The majority of TGCTs (85%-90%) manifest as asymptomatic testicular masses, which can be discovered by the patient, parent, or physician (6,7). Scrotal pain, with or without a mass, has been attributed to intratumorally hemorrhage or infarction in up to 50% of TC cases. In our study, beyond a testicular mass, pain was reported only in 5 postpubertal patients, and only 3 of them had the presence of tumoral necrosis or infarction on the histological report.

The connection between age at diagnosis and histologic characteristics, etiology, treatment strategies, and prognosis has been determined to be substantial (8). The age of 12 is commonly used as a proxy for the onset of puberty. Our cohort precisely matched the described bimodal distribution of disease, with peaks of incidence in both

the first year of life and the seventeenth year. Notably, among prepubertal malignant tumors, only a small proportion (5%) of prepubertal YSTs exhibited dissemination at the time of diagnosis, contrasting with postpubertal GCTs, where the percentage of cases with metastasis at presentation ranges from 20% to 30%. Additionally, nearly 90% of prepubertal children are stage 1 at the first presentation, compared to only 35% of postpubertal cases with testicular-limited cancer. This further demonstrates the highly aggressive and distinct nature of TGCTs in adolescents (9).

Increased AFP values were identified in more than half of the patients included in the study, which contrasts with findings by Kashyap, who observed that among 66 children with abnormally high AFP levels (>20 ng/mL), only 18 (27.3%) showed signs of malignancy (10). Preoperative serum AFP levels ranged from 39 ng/mL to 5321 ng/mL (median 2255 ng/mL) in malignant cases. In prepubertal patients, the AFP value was increased in two YSTs and in one case with an immature teratoma. Based on a meta-analysis, AFP was found to be very useful in distinguishing YSTs in prepubertal age cohorts (median 90%). These values were typically >100 ng/mL, which proved very useful for distinguishing teratomas, as they do not always produce elevated AFP values (11). Elevated hCG values were identified in 6 postpubertal patients included in the study. Regarding the type of tumor, we observed the highest value of hCG (45654 mIU/mL) in the patient with mixed GCT who had metastases at the time of presentation. In the literature, choriocarcinomas had the highest incidence of elevated levels, followed by seminomas (15 to 20%) and EC. It has been shown to be considerably higher in just two boys with mixed GCT in a study involving 34 male patients, leading some published research to conclude that testing for it in prepubertal disease age cohorts is minimally useful (11). Significant increases in LDH, have been linked to high tumor burden and may indicate recurrence (12). Elevated LDH values were identified in six postpubertal patients included in the study.

Imaging plays a significant role in the clinical staging and subsequent restaging of patients with GCTs (13,14). US has been used for all diagnosed patients, with only 7 requiring additional imaging studies. Recently, 18F-FDG PET has been used alongside CT to monitor patients for metastasis or recurrence (15). In our series, PET-CT was performed on 3 postpubertal patients. Considering the findings of some researchers, who reported a high incidence of false-negative PET scans within two weeks of chemotherapy, it is imperative that the examination be performed prior to chemotherapy (16). In our series, we provided a rational use for elucidating its diagnostic significance beyond seminoma.

Pohl *et al*. reported that 74% of the testicular masses identified in the prepubertal group in their research were determined to be benign (17). However, in our study, only one prepubertal patient was diagnosed with a benign lesion, which does not align with findings in existing literature. Previously, it was believed that YSTs were the predominant pathology in prepubescent males. Other research has acknowledged that there may have been selection bias in their report due to the absence of benign mature teratoma lesions among participants (18). In our sample population, we had 4 testicular teratoma with immature tissue and only 3 cases with YST.

A meta-analysis combining studies from IGCCCG and COG revealed excellent 6-year event-free survival (EFS) and overall survival (OS), with EFS of 78.5% and OS of 100% for stage 1, 100% for stage 2, 94.1% for stage 3, and 90.6% for stage 4 (19). In our study, the average OS rate was 94.4%, while the overall progression-free survival rate was 77.8%. Patients in the postpubertal age group had a significantly lower PFS period compared to those in the prepubertal age group. Several investigations in the literature have examined the genetic foundation of male infertility following cancer. These studies shed light on the genetic vulnerability associated with different cancer treatments and explore the possibility of men recovering reproductive function at the end of cancer treatment (20, 21).

Our study has a few limitations. These include the relatively small number of patients, the long-time span (20 years), the retrospective nature of the study, and possible selective bias because our institution is not used as a national referral medical center for TT.

CONCLUSIONS

Testicular tumors form a heterogeneous group that varies considerably in clinical presentation, location, histology, and biology. There is a great necessity to include patients in international partnerships, data exchange, and clinical trials at all stages and risk categories for understanding these uncommon tumors and, most critically, to improve outcomes. This study represents the largest pediatric testicular case series in eastern Romania, emphasizing the significance of ongoing research and collaborative efforts to enhance TC management. Achieving this necessitates further investigation through targeted studies and involvement in clinical trials, particularly given the limited number of worldwide reports.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

INSTITUTIONAL REVIEW BOARD STATEMENT

The study was conducted in accordance with the Declaration of Helsinki, and approved by the Institutional Review Board (or Ethics Committee) of "Sf. Maria" Emergency Children Hospital's (No. 29289/12.10.2022) and the "Grigore T. Popa" University of Medicine and Pharmacy of Iasi Ethics Committee (No. 247/15.12.2022) both approved the publication of this report.

ANALYSIS OF THE IMPACT OF TELEREHABILITATION ON CARDIOVASCULAR RECOVERY IN PATIENTS DIAGNOSED WITH PERIPHERAL ARTERIAL DISEASE OF THE LOWER LIMBS (Abstract): Peripheral arterial disease (PAD) is a significant public health concern, given its debilitating consequences, diminished quality of life (QoL), and the associated increased cardiovascular risk. Cardiac rehabilitation (CR) based on supervised exercise therapy (SET) is recommended as first-line treatment, but the patient adherence to these programs is low. Home-Based Exercise Therapy (HBET) may be an effective alternative, and can be achieved by telerehabilitation (TR), where patients receive exercise recommendations and are monitored remotely using current technological means. **Objectives:** The aim of this study was to analyze the impact of a TR program on the improvement of general health status in patients with PAD. **Materials and methods:** 20 people diagnosed with PAD followed a 12-week TR program based on walking at home with a progressive increase in the number of steps. Physical activity monitoring was performed using electronic devices, and participants' progress was assessed weekly by individual telephone calls with the investigator. Patients were reassessed at the end of the TR intervention. **Results:** Statistically significant improvements were observed in the majority of clinical and paraclinical parameters, alongside functional status, cardiovascular risk, and quality of life of the patients, from baseline to the end of the 12-week training period. **Conclusions:** Home-based exercise therapy monitored with digital technology may be an effective strategy for CR of patients with PAD. **Keywords:** PERIPHERAL ARTERIAL DISEASE, TELEREHABILITATION.

INTRODUCTION

Cardiovascular diseases (CVDs), particularly those of atherosclerotic etiology, are the leading cause of death worldwide (1). Mortality associated with these pathologies has risen by approximately 7.4 million over the past four decades (2), with a balanced distribution between genders (1).

The most common CVDs are coronary artery disease and stroke, followed by peripheral arterial disease (PAD) (3). PAD represents a significant public health issue globally, affecting around 5.6% of adults, with a 72% increase in prevalence observed from 1990 to 2019 (4). The main clinical manifestation of PAD is intermittent claudication (IC), defined by pain or discomfort in the legs, onset on exertion and improving at rest (6). This symptom leads to limitation of functional capacity, thus reducing patients' social participation, quality of life (QoL) and life expectancy (6,7).

In terms of rehabilitative treatment of PAD, supervised exercise therapy (SET) is the first-line recommendation according to the ***European Society of Cardiology Guidelines*** (8), but recent studies have demonstrated low patient adherence to these cardiac rehabilitation (CR) programs (9,10). Consequently, the guidelines offer an alternative approach of home-based exercise therapy (HBET) monitored remotely by electronic devices, telephone communication and logbooks (8). Thus, telerehabilitation (TR) could be a potential way to effectively implement HBET, implying that patients receive recommendations for their exercise program according to their PAD stage, their progress being followed with current technological means by their doctors (11-14).

We conducted a study based on a 12-week home-based exercise program, aiming to analyze the impact of TR on CR in patients diagnosed with PAD.

MATERIALS AND METHODS

Out of a total of 824 patients admitted to a CR clinic between January 1st and March 1st, 2024, 27 were diagnosed with PAD, of whom 20 were enrolled in our study after applying inclusion and exclusion criteria (fig. 1).

The first stage of the study aimed to establish the clinical-paraclinical profile of the patients by performing anamnesis, clinical examination, laboratory tests, 6-minute walk test, cardiopulmonary exercise test, ankle-brachial index measurement, carotid Doppler ultrasound, cardiovascular risk calculation and QoL assessment by specific questionnaire (PADQOL - Peripheral artery disease quality of life, QOLPAD - Quality of life of patients with peripheral artery disease, VASQOL-6 - Vascular quality of life).

We prescribed to each patient a personalized TR program based on walking at home for 12 weeks, with the frequency, intensity and duration of training adapted according to the individual clinical and paraclinical profile. Each participant received an electronic device (smart-watch) for monitoring physical activity and was trained in its appropriate use. An investigator conducted weekly individual telephone calls lasting approximately 10 minutes to assess general health, physical activity, and adherence to treatment, adjusting the exercise program by progressively increasing the number of steps performed daily by approximately 250 steps/day for the following week. Patients were re-evaluated at the end of the 12-week TR program, using the same methods applied at the time of enrollment in the study.

All participants provided written informed consent prior to enrollment in the study. The study protocol was approved by the Ethics Committee of "Grigore T. Popa" University of Medicine and Pharmacy Iași (approval certificate 10.01.2024) and by the Ethics Committee of Iași Clinical Rehabilitation Hospital (approval certificate dated 16.11.2022).

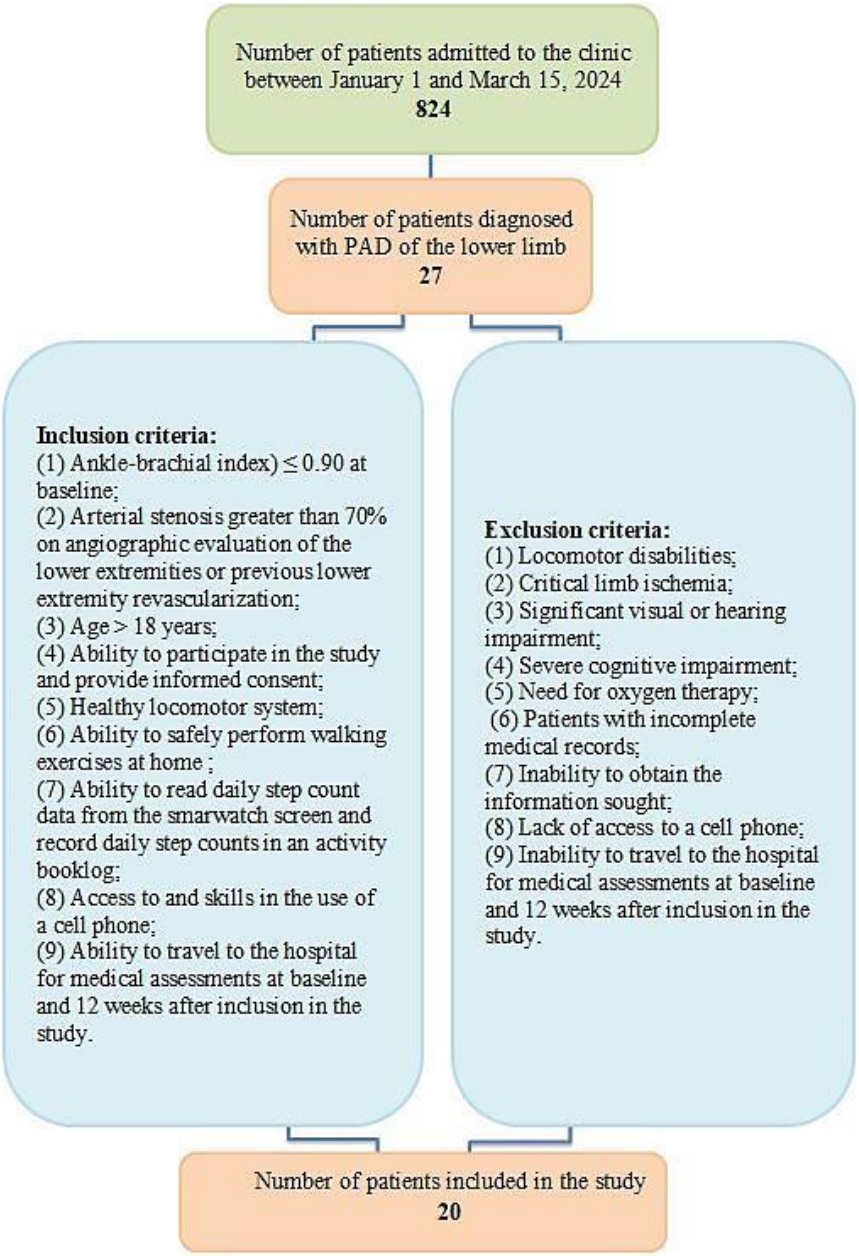

Fig. 1. Criteria for inclusion and exclusion of patients from the study

RESULTS

Of the 20 patients, 15 were male and 5 were female, with a mean age of about 67 years, mostly from rural areas. 40% of the studied population had a PAD course between 1 and 5 years. In terms of behavior, we found a preponderance of smoker or ex-smoker status. Regarding the clinical char-

acteristics of PAD, 80% of patients exhibited symptomatic (effort related) peripheral artery disease and 20% had chronic limb-threatening ischemia.

Concerning associated comorbidities, 80% of the individuals had diabetes mellitus or impaired fasting glucose, 85% hypertension, 15% elevated blood pressure, 40% chronic kidney disease, and 80% obesity or overweight. Additionally, 80% of population had dyslipidemia. A significant proportion of the cohort was diagnosed with heart failure (35%), chronic coronary syndrome (15%), chronic obstructive pulmonary disease (15%), and 10% had a history of stroke. A small proportion of studied population had documented lower limb arterial stenosis (20%) or other arterial stenosis (10%). Carotid atheromatosis was detected at Doppler ultrasonography in 90% of the participants.

Regarding medication, 65% of the patients had oral Cilostazol or Pentoxifylline as treatment and 55% of the patients had previously undergone intravenous treatment in hospital with Alprostadil or Pentoxify-lline. 25% of participants received a medical prescription for oral home treatment with oral Cilostazol or Pentoxifylline.

All 20 patients had completed the TR program and attended the follow-up medical visit at the end of the 12 weeks of training. 5 of these patients had difficulties using the smartwatch, encountering technical problems such as device failure or discharge and thus not fully recording physical activity. These problems were solved by replacing the device or providing additional instructions for its correct use.

After the 12 weeks of walking at home, we found statistically significant decrease in diastolic blood pressure in the study population (tab. I). This reduction can be attributed to improved endothelial function and increased nitric oxide production, leading to vasodilation and reduced peripheral vascular resistance. In contrast, systolic blood pressure remained stable, likely due to its stronger correlation with cardiac output. Walking, as a moderate-intensity aerobic exercise, also improves peripheral vessel elasticity and reduces diastolic pressure more effectively than systolic pressure.

TABLE I.

Changes in the blood pressure values between baseline and 12-week assessment

Parameter	The baseline evaluation	The final evaluation	p
SBP (mmHg)	147.00(131.00;153.00)	137.5(125.00;147.5)	0.841
DBP (mmHg)	78.25 ± 9.34	78.00 ± 8.55	0.003

Diastolic blood pressure – DBP; Systolic blood pressure – SBP.

In addition, we found a statistically significant decrease in body mass index (BMI) (tab. II) and glycemia (tab. III) between baseline and final assessment. This reduction in BMI is linked to increased energy expenditure from physical activity, promoting fat loss. Sustained physical activity improves insulin sensitivity and accelerates metabolism, contributing to better weight management and glycemic control, particularly in individuals with diabetes or impaired fasting glucose.

TABLE II.

Changes in the body mass index values between baseline and 12-week assessment

Parameter	The baseline evaluation	The final evaluation	p
BMI (kg/m²)	29.02 ± 4.87	28.62 ± 4.48	0.000

Body mass index – BMI.

TABLE III.

Changes in the glucose profile between baseline and 12-week assessment

Parameter	The baseline evaluation	The final evaluation	p
BG (mg/dL)	117.90(106.85;137.90)	118.55(96.00;131.15)	0.022
HbA1c (%)	6.23(5.89;7.33)	6.18(5.74;7.23)	0.003

Blood glucose – BG; Glycated hemoglobin – HbA1C.

At the end of the TR program, improvements in the lipid profile were observed (tab. IV), attributed to a combination of a hygienic-dietary regimen and medication. The diet reduced intake of saturated fats and cholesterol, while hypolipidemic treatment inhibited cholesterol synthesis in the liver.

Additionally, physical activity stimulates the enzymes responsible for the catabolism of low-density lipoproteins (LDL) and increases the levels of high-density lipoproteins (HDL), which contributes to a decrease in total cholesterol (TC) and LDL.

TABLE IV.

Changes in the lipid profile between baseline and 12-week assessment

Parameter	The baseline evaluation	The final evaluation	p
TC (mg/dL)	181.00 ± 40.70	171.86 ± 43.83	0.024
HDL-C (mg/dL)	51.70(48.50;62.15)	48.65(44.85;67.85)	0.001
LDL-C (mg/dL)	108.13 ± 36.07	100.82 ± 37.29	0.039
TG (mg/dL)	119.15(95;142.10)	111.10(91.25;148.16)	0.000

HDL-cholesterol - HDL-C**;** LDL cholesterol – LDL-C; Total cholesterol – TC; Triglyceride – TG.

Inflammatory markers such as erythrocyte sedimentation rate (ESR) and white blood cell count (WBC) significantly decreased (tab. V). This can be explained by the anti-inflammatory effects of moderate exercise like walking, which lowers pro-inflammatory cytokines as TNF-alpha and IL-6, and increases the production of adiponectin, an anti-inflammatory protein. A balanced diet further aids in reducing systemic inflammation.

The improvement in serum iron values (tab. VI) after completing the TR program may be the result of reduced inflammation, which improves iron bioavailability. In the presence of chronic inflammation, hepcidin is increased, which limits iron absorption and release from stores. As inflammation is reduced by exercise and diet, hepcidin levels decrease, allowing more efficient utilization of iron from stores and improved intestinal absorption.

Kidney function also improved, as seen by reduced urea and creatinine levels and enhanced creatinine clearance (tab. VII). This improvement is likely due to better blood flow, reduced oxidative stress, and improved glycemic control, which support kidney health over time.

Carotid Doppler ultrasound showed a stationary state of carotid atheromatosis post-TR intervention, likely due to the short duration being insufficient for visible plaque changes. The TR program improved inflammation and lipid profiles, stabilizing plaques without altering their size, while advanced plaques resist rapid changes and need more time to regress.

TABLE V.

Changes in the inflammatory status between baseline and 12-week assessment

Parameter	The baseline evaluation	The final evaluation	p
CRP (mg/dL)	0.82 ± 0.58	0.69 ± 0.39	0.338
ESR (mm/h)	12.5 (9.5;28.5)	11.5(9;24.5)	0.000
WBC (x10³/mm³)	6.94 ± 2.09	7.25 ± 2.06	0.000

C-reactive protein – CRP; Erythrocyte sedimentation rate – ESR; WBC – white blood cell.

TABLE VI.

Investigation of anemia syndrome at baseline and 12-week assessment

Parameter	The baseline evaluation	The final evaluation	p
Hb (g/dL)	12.93 ± 1.70	13.43 ± 1.32	0.000
Fe (µg/dL)	74.98 ± 29.59	75.12 ± 25.54	0.022

Hemoglobin – Hb; Serum iron – Fe.

TABLE VII.

Changes in the renal function between baseline and 12-week assessment

Parameter	The baseline evaluation	The final evaluation	p
Urea (mg/dL)	43.70(38.90;51.60)	39.91(34.15;48.60)	0.000
Cr (mg/dL)	1.07(0.92;1.27)	1.06(0.98;1.29)	0.001
Cr clearance (ml/min)	66.09 ± 12.62	63.96 ± 13.60	0.001

Creatinine – Cr; Creatinine clearance – Cr clearance.

In terms of functional status, there was an improvement in the onset threshold of IC (tab. VIII), an increase in the walking distance on the 6-minute walk test (6MWT) (tab. IX), and in exercise capacity assessed by cardiopulmonary exercise testing (CPET) (tab. X). QoL as assessed by PADQOL, QOL PAD, VASQOL-6 (tab. XI), and 10-year CV risk (tab. XII) were statistically significantly improved between the two assessments. The improvements can be attributed to regular physical activity, which enhances blood flow and perfusion to peripheral tissues, thereby alleviating symptoms of IC. Continuous exercise promotes cardiovascular adaptations, leading to increased aerobic capacity and endurance. Furthermore, physical activity reduces systemic inflammation and improves lipid profiles, positively influencing overall QoL. These physiological changes collectively contribute to a significant reduction in long-term cardiovascular risk, supporting better health outcomes for participants.

TABLE VIII.

Changes in the onset threshold of intermittent claudication and in the ankle-brachial index value between baseline and 12-weeks assessment

Parameter	Baseline evaluation	Final evaluation	p
The onset of IC (m)	192.50 ± 163.92	484.00 ± 687.93	0.000
Right ABI	0.76 ± 0.17	0.76 ± 0.19	1.000
Left ABI	0.75 ± 0.19	0,75 ± 0.17	1.000

ABI - ankle-brachial index; IC - intermittent claudication.

TABLE IX.

Changes in the in the walking distance and symptom-free walking time on the 6-minute walk test

Parameter	Baseline evaluation	Final evaluation	p
Distance (m)	175.00(110.00;275.00)	250.00(135.00;450.00)	0.000
Duration (min)	6.00(3.50;6.00)	6.00(6.00;6.00)	0.541

TABLE X.

Changes in the exercise capacity assessed by cardiopulmonary exercise testing

Parameter	Baseline evaluation	Final evaluation	p
Maximum LOE (Watt)	73.50(65.50;105.00)	78.00(71.00;107.50)	0.000
VE/VCO2	39.14 ± 11.14	42.07 ± 12.83	0.000
Target HR (bpm)	88.00(78.00;96.00)	89.00(83.00;100.00)	0.004

HR – heart rate; Level of effort – LOE; VE/VCO2 -ventilation/carbon dioxide production slope.

TABLE XI.

Changes in the quality of life between baseline and 12-week assessment

Parameter	Baseline evaluation	Final evaluation	p
VASQOL6 (points)	13.65 ± 3.23	18.50 ± 2.50	0.006
QOLPAD (points)	38.35 ± 6.96	46.05 ± 3.99	0.003
PADQOL (points)	120.80 ± 25.34	149.90 ± 18.60	0.002

PADQOL – Peripheral artery disease quality of life questionnaire;
QOLPAD - Quality of life of patients with peripheral artery disease questionnaire,
VASQQOL6- Vascular quality of life questionnaire.

TABLE XII.

Changes in the cardiovascular risk at 10 years

Parameter	Baseline evaluation	Final evaluation	p
10-years CR (%)	27.43 ± 17.95	25.19 ± 15.82	0.000

CR – cardiovascular risk.

Evaluation of adherence to the TR program showed that during the 12 weeks, 55% of the time patients achieved the target number of daily steps set for the following week, 59% of the time they increased the average number of steps / days compared to the previous week, 55% of the time they averaged more than 5,000 steps/day, and 11% of the time they averaged more than 10,000 steps/day (tab. XIII).

TABLE XIII.

Adherence to the telerehabilitation program

Target	% of time
Achievement of average number of target steps/day set for the following week	55.49 ± 35.65
Increase in average steps/day compared to last week	58.74 ± 9.55
Average more than 5 000 steps/day	55.46 ± 42.36
Average more than 10 000 steps/day	11.29 ± 26.37

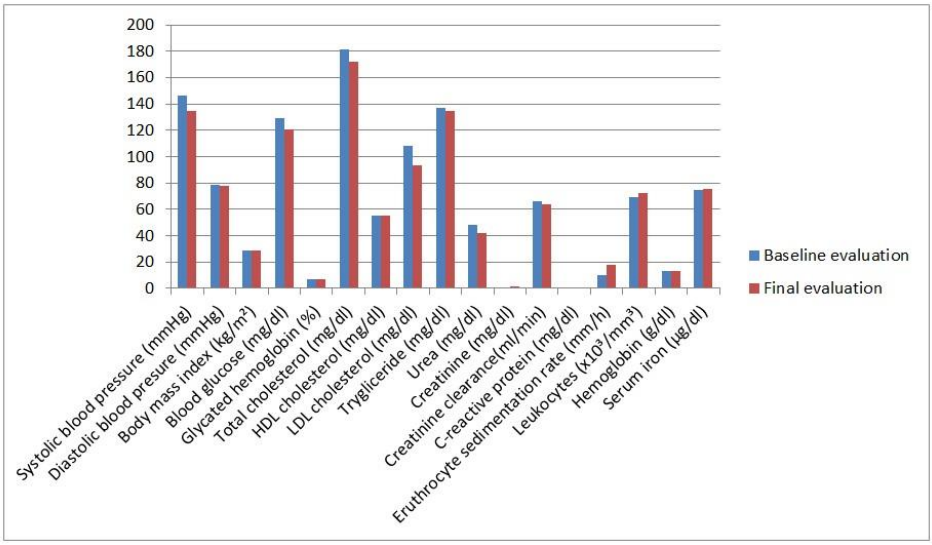

Fig. 2. Changes in the clinical-paraclinical profile between baseline and final evaluation

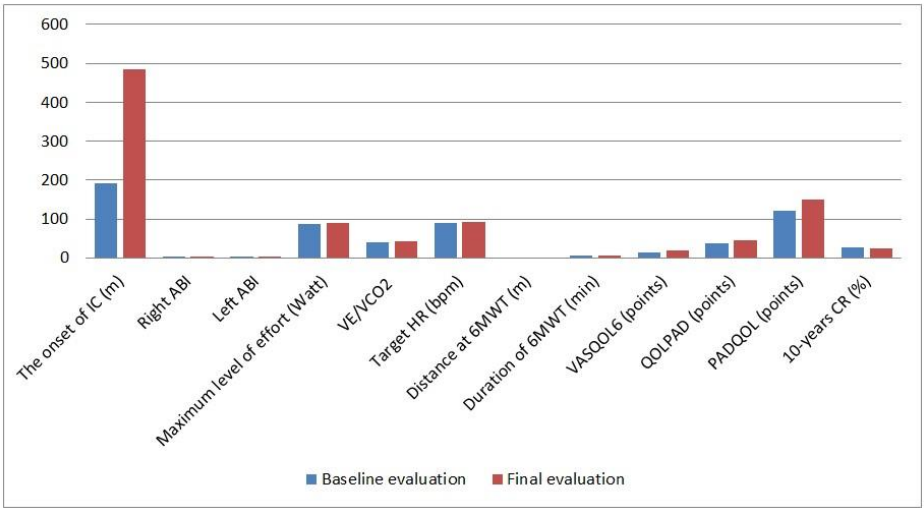

Fig. 3. Changes in functional capacity, quality of life and cardiovascular risk at 10 years between baseline and final evaluation

DISCUSSION

Telerehabilitation, an innovative method of delivering rehabilitation services through digital technologies, has demonstrated multiple benefits in CR of patients with PAD of the lower limbs.

Faster social and family reintegration

A key aspect of TR is that patients are not limited to regular visits to CR centers, as it is the case in SET, allowing them to spend more time at home with their families. This is important because early reintegration into the community and family supports patients' emotional and psychological health. Varnfield M *et al*. (2014) conducted a study in which patients engaged in a home-based rehabilitation program following acute myocardial infarction, in which smartphones were used. The authors demonstrated that the patients had a rapid reintegration into social and family life. This has profound implications for the patient's emotional support and motivation to continue the rehabilitation program in the long term (15).

Reduction of hospitalization-dependent depression and anxiety

TR reduces the need for frequent hospitalization and stressful interactions with the medical field, which can aggravate anxiety and depression associated with chronic diseases. A study by Frederix *et al*. highlighted the positive effect of TR in reducing levels of anxiety and depression among patients with CVDs, including those with PAD. Lack of dependence on hospitalization and continuous monitoring through TR helped to decrease patients' psychological distress, thus improving not only physical but also emotional recovery (16).

Increased functional and self-care capacity

Another significant benefit is the increased functional capacity of patients. TR gives them the possibility to manage their exercise program under remote supervision of specialists. Research conducted by Duscha *et al*. (17) and Schopfer (18) has shown a notable improvement in exercise tolerance and walking ability among patients with cardiovascular diseases who underwent TR interventions. These findings were similar to the ones observed in our study. Also, in two studies on the effects of TR in patients with acute myocardial infarction and coronary artery disease, respectively, an increase in self-care capacity was observed by developing skills necessary for long-term disease management (19, 20).

Increasing quality of life

QoL is a key aspect in evaluating the success of a rehabilitation program. TR allows a personalized and flexible recovery, reducing the discomfort and effort associated with frequent travels to rehabilitation centers. Otsuka at al observed a significant improvement in QoL assessment scores in PAD patients who underwent a HBET program after endovascular treatment (22). In our study we obtained similar results regarding the improvement of QoL assessed by specific questionnaires for patients with PAD, after the home rehabilitation program. The increase in patient satisfaction could be due to the fact that they are able to participate more actively in their social and family life and are able to maintain their daily routine with fewer interruptions.

Decreased cardiovascular risk and adverse events

Another important aspect of TR is its impact on cardiovascular risk reduction. In our research we that estimated cardiovascular risk decreased in 10 years. Our results are similar to the findings of the recent study by Kunutsor and Laukkanen, which demonstrated the role of physical activity in reducing the risk of major cardiovascular events in patients with pre-existing CVDs, including PAD (22). In addition, TR allows constant monitoring of clinical parameters and adaptation of the exercise program according to patients' responses, which offers the advantage of earlier intervention in case of cardiovascular complications.

Case stratification and hospitalization only of patients who need it

Another important benefit of TR for people with PAD is the ability to continuously monitor patients' health status and stratify cases according to severity. By using telemonitoring technologies, specialists can obtain real-time data on vital parameters and functional evolution of patients, which allows a more accurate assessment of the need for hospitalization or treatment adjustment. In this context, telerehabilitation can significantly reduce the number of hospitalizations by focusing medical resources on patients who really need intensive care in hospital. According to a study by Scherrenberg *et al*, remote monitoring allows early identification of signs of worsening disease and rapid adjustment of therapy without the need for hospitalization. In the same study, it was highlighted that patients with PAD monitored by TR had significantly fewer hospitalizations compared to those who followed conventional CR (23).

Reduced costs and optimization of human resource requirements

One of the major advantages of TR in CR of patients with PAD is the significant decrease in costs associated with treatment. The implementation of TR significantly reduces direct costs, including patient transportation to rehabilitation centers, hospital room and board expenses, and the intensive use of hospital equipment and infrastructure. In a study conducted by Cottrell *et al.*, TR was shown to reduce costs per patient by approximately 30-50% compared to conventional CR (24). This cost reduction can make rehabilitation accessible to a larger number of patients, especially in countries or regions with limited medical resources.

In addition, TR reduces the need for human resources involved in the rehabilitation process. In traditional CR, each patient requires frequent and direct interactions with a team of physicians, physiotherapists, nurses and other specialists. By remotely monitoring and guiding patients through automated programs or mobile applications, telerehabilitation allows medical teams to manage multiple patients simultaneously with the same resources. A study by Kraal *et al.* showed that medical staff were able to monitor and coordinate twice as many patients through telerehabilitation compared to traditional treatments without compromising quality of care (25).

Also, reducing the need to be physically present in medical facilities for constant monitoring, frees the hospital staff to focus on critical cases, which contributes to the overall efficiency of the healthcare system. In the context of increasing demand for healthcare services and staff shortages, telerehabilitation is becoming a practical solution to optimize available resources

and improve access to treatment for the largest possible number of patients.

CONCLUSIONS

HBET performed by using digital technology is an effective approach for CR in patients with PAD. TR programs require adaptation according to the clinical and paraclinical profile and psycho-emotional status of the patients to maximize benefits. Such individualized therapeutic interventions could provide significant benefits, including faster social and family reintegration, reduced levels of anxiety and depression associated with hospitalization, improved functional capacity and self-care skills, decreased cardiovascular risk and thus increased life expectancy, contributing to improved QoL of patients with this pathology. In terms of the public health system, TR could reduce the need for hospitalizations and the human resources involved in the treatment of patients with BAP, providing an efficient and sustainable approach for remote care and stratification of case severity, with identification of those requiring hospitalization.

EFFICACY OF COMPUTER-ASSISTED COGNITIVE STIMULATION IN PSYCHIATRIC DISORDERS: CORRELATIONS BETWEEN DIAGNOSIS, TREATMENT AND EVOLUTION OF COGNITIVE SCORES (Abstract): This study **aims** to investigate the effectiveness of computer-assisted cognitive stimulation (CACS) in improving cognitive deficits associated with psychiatric disorders. **Materials and methods:** The study evaluated the impact of the CACS intervention on cognitive functions using standardized instruments such as the Mini-Mental State Examination (MMSE) and the Montreal Cognitive Assessment (MoCA). In addition, the influence of diagnosis and demographic variables on the results obtained was analyzed, highlighting significant variations depending on the typology of the psychiatric disorder treated. **Results:** The data indicate considerable improvements in the cognitive domain, with differences between diagnostic groups highlighting the importance of a differentiated approach. **Conclusions:** The results support the need for personalization of interventions and highlight the relevance of assessing qualitative factors in the application of CACS, opening new research directions for optimizing the treatment of psychiatric disorders through cognitive technology.
Keywords: COMPUTER-ASSISTED COGNITIVE STIMULATION (CACS), PSYCHIATRIC DISORDERS, COGNITIVE ASSESSMENT, MMSE, MOCA.

INTRODUCTION

Psychiatric disorders, such as depression and schizophrenia are often associated with profound cognitive deficits, which significantly impact the quality of life of patients. These cognitive impairments not only occur frequently but also vary depending on the type of disorder, the patient's age and the severity of symptoms (1). In particular, the importance of cognitive assessment has been emphasized in the context of neurodegenerative diseases, for example, (2) highlight the

essential role of standardized instruments, such as Mini-Mental State Examination (MMSE) and Montreal Cognitive Assessment (MoCA), in identifying cognitive deficits which are sometimes not detectable by conventional clinical assessments.

Non-pharmacological interventions, such as computer assisted cognitive stimulation (CACS) have shown considerable potential in improving these deficits. Recent studies suggest that the effects of CACS may be influenced by factors such as the specific diagnosis, age and intensity of the intervention. (3) and (4) showed that the response to CACS varies depending on the clinical characteristics of the patients and (5) reported moderate improvements in cognitive function, although with notable differences between different psychiatric disorders (6).

These findings highlight the need for personalized interventions, adapting them to the particularities of each patient to maximize cognitive benefits.

Another aspect of interest is the impact of age on the effectiveness of CACS (7) found that age is not always a robust predictor of intervention outcomes, suggesting that variables such as the number of sessions and the severity of initial cognitive deficits may play a more determining role. In this regard, (8) demonstrated that an increased number of CACS sessions is associated with significant improvements in MMSE and MoCA scores, highlighting a positive relationship between the intervention and cognitive performance.

Therefore, analyzing the efficacy of CACS, assessed changes in MMSE and MoCA scores, as well as investigating the influence of diagnosis and other factors (age, number of sessions) on cognitive outcomes, are crucial for the development of personalized and evidence-based therapeutic strategies in the treatment of cognitive deficits associated with psychiatric disorders.

MATERIALS AND METHODS

This study included 92 patients with psychiatric disorders. Inclusion criteria for selecting patients with a confirmed diagnosis of psychiatric disorders who had participated in a minimum of 10 sessions of computerized cognitive stimulation. Exclusion criteria included the presence of major comorbidities that could influence the assessment of cognitive function, the inability to provide informed consent and the existence of severe medical conditions requiring urgent interventions. These patients completed at least 10 sessions of CACS. Diagnoses were numerically coded to facilitate statistical analysis (e.g., 1 - emotionally unstable personality disorder, 2 - bipolar affective disorder - depressive episode, 3 - severe depressive episode - generalized anxiety disorder). In the first table is presented the full list of psychiatric conditions included in the study.

Patients were selected according to the inclusion and exclusion criteria established in the study protocol.

Cognitive function was assessed using the MMSE and MoCA, both before and after CACS intervention. The number of CACS sessions ranged from 3 to 233, depending on the protocol individualized for each patient.

The procedure included an initial assessment of patients using MMSE and MoCA, followed by CACS, with a frequency of 1-2 sessions per week, each session lasting 60 minutes.

After completing the CACS session, patients were re-assessed using the same cognitive scales.

TABLE I.

Psychiatric diagnoses included in the study and numerical coding

Numeric code	Diagnostic
1	Emotionally unstable personality disorder
2	Bipolar affective disorder - depressive episode
3	Severe depressive episode, Generalized anxiety disorder
4	Depressive episode with anxiety elements
5	Severe depressive episode
6	Organic mood disorder
7	Mixed dementia, Recurrent depressive disorder
8	Acute psychotic disorder with schizophrenia symptoms
9	Recurrent depressive disorder, severe current episode
10	Mixed dementia, Recurrent depressive disorder
11	Generalized anxiety disorder, Obsessive-compulsive disorder
12	Severe depressive episode with atypical features
13	Mild cognitive disorder
14	Atypical autism
15	Mixed dementia - mild form
16	Paranoid schizophrenia
17	Attention and activity disorder
18	Dependent personality disorder
19	Recurrent depressive disorder - severe current episode
20	Recurrent depressive disorder - current episode moderate
21	Dementia in early-onset Alzheimer's disease
22	Emotionally unstable personality disorder, Mild depressive episode
23	Generalized anxiety disorder, Depressive episode with atypical features
24	Panic disorder, Mild depressive episode, Mixed dementia
25	Recurrent depressive disorder - current moderate episode with psych cognitive features
26	Severe depressive episode, generalized anxiety disorder, Sleep disorder
27	Recurrent depressive disorder - current moderate episode, Nonorganic insomnia
28	Mild depressive episode, Adjustment disorder
29	Mild cognitive disorder, Anxiety disorder
30	Recurrent depressive disorder
31	Emotionally unstable personality disorder
32	Adjustment disorder, Nonorganic insomnia
33	Mild cognitive disorder, Moderate depressive episode, Paroxysmal anxiety disorder
34	Posttraumatic stress disorder

Numeric code	Diagnostic
35	Recurrent depressive disorder - mild current episode
36	Anxiety disorder, Recurrent depressive disorder - moderate depressive episode
37	Mixed anxiety and depressive disorder
38	Mixed dementia, Organic personality disorder, Severe depressive episode
39	Cognitive disorder, Recurrent depressive disorder, Generalized anxiety disorder
40	Recurrent depressive disorder - severe current episode without psychotic symptoms
41	Recurrent depressive disorder - severe current episode without psychotic symptoms, Generalized anxiety disorder
42	Mild depressive episode, Panic disorder
43	Moderate depressive episode
44	Panic disorder
45	Cognitive disorder, Severe current depressive episode with psychotic symptoms
46	Cyclothymia
47	Bipolar affective disorder - depressive episode, Cognitive disorder
48	Anxiety disorder, Mild depressive episode
49	Sleep disorder
50	Schizophrenia
51	Emotionally unstable personality disorder, Anxiety disorder
52	Cognitive disorder, Chronic organic cerebral disorder
53	Moderated mixed dementia, Moderate depressive episode
54	Moderate depressive episode with anxious - interpretive elements
55	Moderated mixed dementia, Severe depressive episode
56	Late-onset *alz*heimer's disease dementia
57	Sexual identity disorder, Disturbance of attention and activity
58	Mixed dementia, Recurrent depressive disorder - severe current episode
59	Cognitive disorder
60	Mixed dementia

Statistical analyses included the paired-samples t-test used to compare MMSE and MoCA scores before and after the intervention, to determine whether there was a significant improvement in cognitive function. One-way ANOVA was used to compare differences between diagnostic groups in terms of MMSE and MoCA scores. Pearson correlations were calculated to assess the relationship between age, number of CACS sessions and differences in cognitive scores (ΔMMSE and ΔMoCA).

All personal data of patients were stored and processed in accordance with GDPR regulations. Patients signed an informed consent agreement regarding the processing of personal data. The data were stored electronically in digital form using the *Mi-*

crosoft Excel program, ensuring confidentiality and security of the information.

RESULTS

The study aimed to evaluate the effects of the CACS intervention on cognitive function, using two internationally recognized instruments: MMSE and MoCA. The results indicate a clear improvement in cognitive performance, illustrated both by the increase in the mean scores and by the statistical significance of the observed changes.

Specifically, the mean score on the MMSE test improved from 25.17, recorded before the intervention, to 26.33 after its application. This increase is supported by a t-statistic of -3.686 and a p-value of 0.000386, which means that the probability that the observed difference is due to chance is practically negligible. In addition, a correlation coefficient of 0.798 between the pre- and post-intervention scores confirms the existence of a strong linear relationship, indicating that the initial performance is a good predictor of subsequent cognitive improvement. Similarly, for the MoCA test, there was an increase in mean scores from 24.29 to 26.40. This difference is marked by a t-statistic of -10.737 and extremely small p-values (p one-tail = 3.72453x10^(-18) and p two-tail = 7.44906x10^(-18)), which emphasizes that the improvement is not attributable to chance. A correlation coefficient of 0.909 between pre- and post-intervention measurements highlights an almost perfect association, demonstrating the consistency and robustness of the cognitive improvements.

Statistically, an exceedingly small p-value indicates that the differences between measurements are significant and unlikely to arise from chance, which validates the effectiveness of the CACS intervention. Also, the remarkably high correlation coefficients (0.798 for MMSE and 0.909 for MoCA) reflect a close and predictive relationship between cognitive performance before and after the intervention, thus confirming the positive impact of applied method.

ANOVA analysis revealed that the specific diagnosis of the patients significantly influences cognitive performance, with an F of 142.86 ($p \approx 1.12x10^{(-24)}$) for MMSE scores and 133.58 ($p \approx 1.59x10^{(-23)}$) for MoCA scores. In addition, the correlation analyses between age and score variations (ΔMMSE and ΔMoCA) generated coefficients close to zero (approximately -0.00739 and -0.03891), indicating that age does not play a determining role in the evolution of cognitive performance post-intervention. Similarly, the weak relationship between the number of CACS sessions and changes in scores ($r = 0.01645$ for ΔMMSE and $r = -0.03203$ for ΔMoCA) suggests that the intensity of the intervention, measured by the number of sessions, is not a significant predictor of cognitive improvement.

For a visual understanding of the relationship between the studies variables, the following graphs were developed.

This graph shows the distribution of MMSE score variations according to age, highlighting a very low correlation coefficient ($r \approx -0.00739$). Thus, it can be concluded that the age factor does not have a significant impact on cognitive improvement, suggesting that the benefits of CACS apply uniformly across the age range of patients.

Similarly, this graph indicates a correlation coefficient of approximately -0.03891, confirming that age differences are not

associated with significant variations in MoCA scores. This finding supports the idea that the intervention produces positive results regardless of the age group.

Visual analysis of the data shows a weak correlation (r = 0.01645) between the number of sessions and MMSE score improvement. This observation suggests that although the number of sessions varies significantly between patients, the intensity of the interventions is not a direct predictor of cognitive improvement measured by MMSE.

Similarly, the analysis of the relationship between the number of sessions and the variation of MoCA scores indicates a non-significant correlation coefficient (r = -0.03202). This confirms that intensity (in terms of number of sessions) does not directly influence cognitive outcomes and other variables, such as the specificity of the diagnosis or individual characteristics of the patients, may play a more determining role.

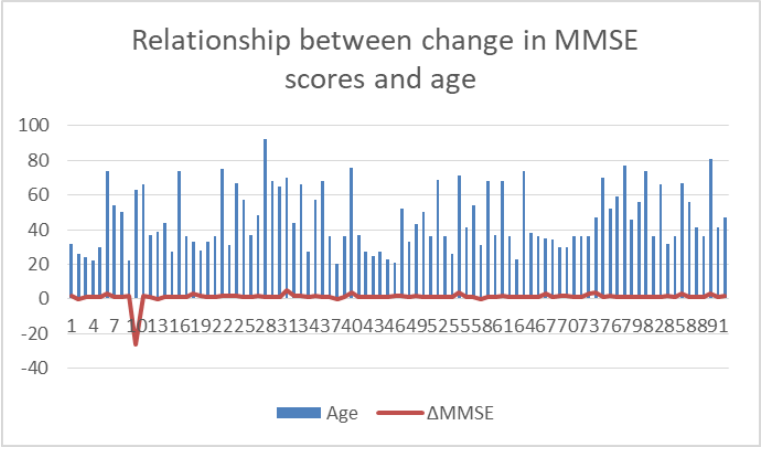

Fig. 1. Relationship between change in MMSE scores and age

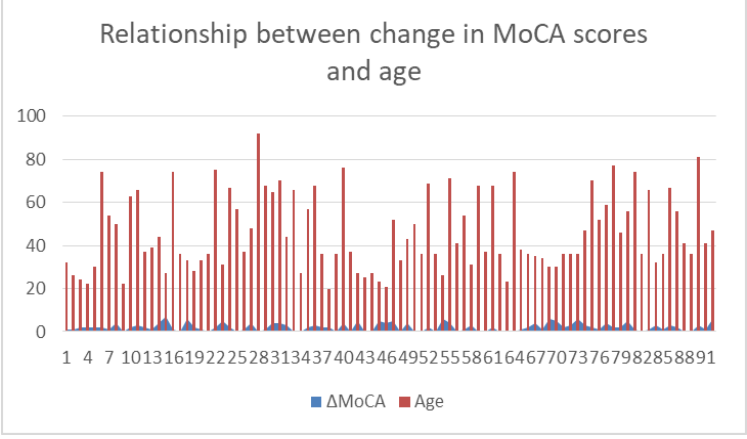

Fig. 2. Relationship between change in MoCA scores and age

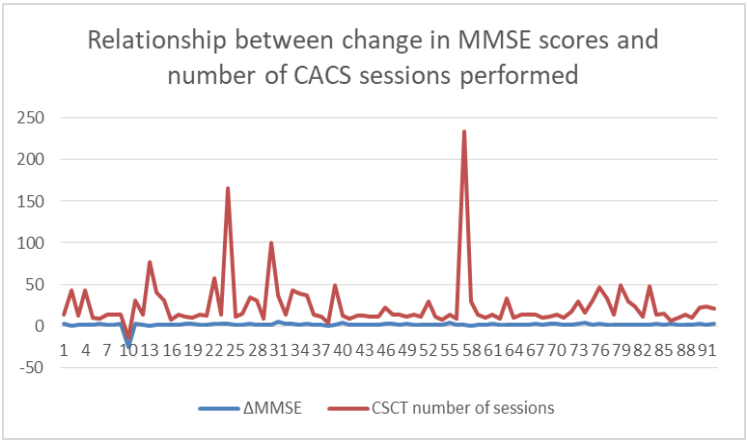

Fig. 3. Relationship between change in MMSE scores and number of CACS sessions performed.

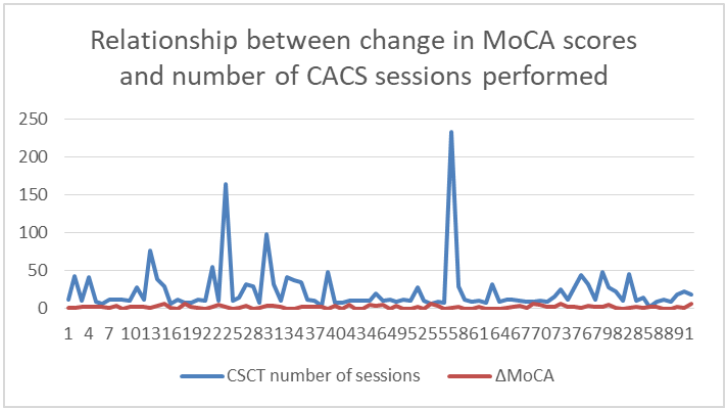

Fig. 4. Relationship between change in MoCA scores and number of CACS sessions performed.

Thus, the CACS intervention generated significant increases in cognitive function, and the statistical values obtained confirm both the real significance of these changes and the consistency of the improvements, demonstrating the effectiveness of the method within the study.

DISCUSSION

The study clearly highlights that CACS intervention leads to significant improvements in cognitive function, as reflected in the notable increase in MMSE and MoCA scores post-intervention. Paired-samples t-tests showed a significant mean difference: MMSE scores increased from 25.17 to 26.33 ($t = -3.686$; $p = 0.000386$; $r = 0.798$), and MoCA scores improved from 24.29 to 26.40 ($t = -10.737$; p one-tail $\approx 3.72 \times 10^{-18}$, p two-tail $\approx 7.45 \times 10^{-18}$; $r = 0.909$). ANOVA analysis also demonstrated that specific diagnosis has a significant impact on cognitive performance, with very high F-values ($F = 142.86$ for MMSE and $F =$

133.58 for MoCA, with $p < 0.001$ in both cases). These findings are in line with the literature, which supports that CACS can bring relevant benefits, but the response to treatment varies depending on the patient's diagnostic profile (3, 4).

The graphs completed the statistical analysis and provided additional visual interpretation. Figure 1 illustrates the relationship between age and ΔMMSE, and Figure 2. shows the relationship between age and ΔMoCA; both graphs highlight the correlation coefficients close to 0 ($r \approx -0.00739$ and $r \approx -0.03891$, respectively), confirming that age is not a significant predictor of improvement in cognitive function. Similarly, Figure 3 and Figure 4 show the relationship between the number of CACS sessions and the changes in scores (ΔMMSE and ΔMoCA) and the results show a very weak correlation ($r = 0.01654$ for ΔMMSE and $r = -0.03203$ for ΔMoCA). These observations suggest that, although it can be assumed that a higher intensity of the intervention could lead to superior outcomes, the number of sessions per se is not a significant predictor of cognitive improvements in this study.

Therefore, in the current context, the results demonstrate that the beneficial effects of CACS are determined by the specificity of the diagnosis rather than by demographic factors or the intensity of intervention, thus opening the way for future investigations to explore other moderating factors, such as the quality of the sessions or the initial stage of cognitive deficits. These aspects, highlighted both by statistical analysis and graphical representations, will be subject to detailed analysis in future discussions, thus providing a solid basis for optimizing non-pharmacological interventions in the management of cognitive deficits in patients with psychiatric disorders.

Despite the encouraging findings related to CACS, several limitations of the current study must be acknowledged. First, the inherent heterogeneity of psychiatric disorders and the variability in cognitive impairments among patients complicate the evaluation of CACS efficacy (9, 10. Many of the existing studies have been conducted with relatively small sample size and without rigorous control groups, which limits the generalizability of their findings (11, 12. Additionally, the reliance on self-reported measures of cognitive functioning may introduce bias, as patients' insight into their own cognitive deficits can vary considerably (13).

Furthermore, the current literature often does not adequately account for confounding variables such as medication effects, comorbid conditions and socio-demographic factors, all of which can significantly influence cognitive outcomes (14, 15). Future studies should strive to address these limitations by recruiting larger, more diverse samples and incorporating objective measures of cognitive functioning alongside self-report instruments (16, 17).

The promising efficacy of computer-assisted cognitive stimulation (CACS) in psychiatric disorders opens several exciting avenues for future research. As psychiatric treatment continues to advance, integrating CACS with conventional therapeutic modalities may further enhance cognitive outcomes in patients with diverse psychiatric conditions. Future investigations should prioritize longitudinal studies that examine the long-term effects of CACS on both cognitive functioning and psychiatric Symptoms, especially in populations with comorbid conditions (18, 19. In addition, employing advanced neuroimaging techniques to explore the neurobiological mechanisms underlying CACS may shed light on its influence on brain function and

structure (20).

Moreover, the potential constructive interaction of combining CACS with non-invasive brain stimulation methods, such as transcranial magnetic stimulation (TMS) or deep brain stimulation (DBS), merits further exploration. Early evidence suggests that these combined approaches can amplify cognitive improvements and alleviate psychiatric symptoms (21, 22, 23).

This study has some limitations that need to be considered. First, the retrospective design may introduce biases related to the selection and quality of the available data. Second, the sample size and diversity of the study population may limit the generalizability of the results. Also, the lack of a control group reduces the ability to attribute direct causality to the intervention. In addition, variables such as treatment adherence and socio-economic factors were not controlled for, which could influence the results obtained.

CONCLUSIONS

The present study provides compelling evidence that CACS exerts a significant positive impact on cognitive function among patients with psychiatric disorders. Our statistical analyses revealed that both MMSE and MoCA scores improved markedly following the intervention, thereby confirming the clinical efficacy of CACS. Notably, the data indicates that the specific psychiatric diagnosis plays a pivotal role in determining cognitive outcomes, underscoring the importance of tailoring interventions to the individual's clinical profile. In contrast, neither age nor the number of cognitive stimulation sessions exhibited a significant correlation with the magnitude of cognitive improvements, suggesting that the therapeutic benefits of CACS remain consistent across different demographic groups and intervention intensities.

These findings advocate for the advancement of personalized CACS protocols, wherein interventions are adapted to the unique cognitive profile and diagnostic characteristics of patients. Future research should focus on refining these personalized approaches, as well as on exploring additional factors that might modulate treatment efficacy to ultimate optimize cognitive outcomes in psychiatric populations.

BODY MASS INDEX- MORE THAN JUST A NUMBER IN THE PROGNOSIS OF PATIENTS WITH COPD AND METABOLIC SYNDROME (Abstract): Chronic obstructive pulmonary disease (COPD) is increasingly recognized as a complex systemic disease rather than a condition limited to the lungs. Malnutrition, cachexia, and obesity contribute to decreased exercise capacity, higher rates of exacerbations and increased mortality. The **aim** of the study was to investigate the influence of the body mass index (BMI) on the prognosis of patients diagnosed with COPD, in the presence or absence of MetS. **Materials and methods**: A total of 100 patients with a confirmed diagnosis of COPD were enrolled in the study, of whom 65 patients met the diagnostic criteria for MetS. Patients were evaluated based on clinical, anthropometric, and laboratory parameters. BMI was calculated for each patient, and its association with disease prognosis was subsequently analyses, considering the presence or absence of MetS. **Results:** The patients were divided into two groups based on the presence or absence of metabolic syndrome. Both BMI and waist circumference showed statistically significant differences between groups ($p<0.001$). Plasma glucose levels were significantly higher in COPD patients with MetS and BMI$\geq$ 25 kg/m^2 compared to those without MetS ($p= 0.020$). Plasma triglyceride levels were also significantly higher in the same group ($p= 0.034$). No statistically significant differences were observed for systolic and diastolic blood pressure across the groups ($p> 0.05$). **Conclusions:** Continuous monitoring of BMI and the prevention of cachexia are essential strategies for reducing mortality rates, whereas the prevention of obesity contributes to the reduction of cardiovascular complications. **Keywords**: COPD, METABOLIC SYNDROME, BMI, PROGNOSIS.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is a major global health problem, characterized not only by persistent respiratory symptoms and airflow limitation, but also by significant systemic effects (1, 2).

Among these systemic manifestations, nutritional disturbances such as malnutrition, sarcopenia, and obesity have been increasingly recognized as important factors influencing disease progression and prognosis (3-5).

In particular, body composition abnormalities and the presence of metabolic syndrome (MetS) are highly prevalent among COPD patients and are associated with increases morbidity and mortality (6, 7). Therefore, assessing and addressing nutritional status represents a crucial component of comprehensive COPD management (8). Moreover, the coexistence of MetS adds a substantial burden of cardiovascular morbidity. As pulmonary function worsens, COPD patients often reduce their physical activity levels, creating conditions that facilitate weight gain (9, 10). In COPD patients, there exists a paradox where individuals with higher body mass index (BMI) tend to have better survival rates than those with normal or low BMI, especially among those with advanced disease (11). One possible reason is that the severity of COPD may be overestimated in obese patients due to the physiological reduction in lung volumes (12).

However, when factors such as carbon dioxide levels, muscle mass, and exercise capacity are accounted for, this "obesity paradox" often disappears (13). Both physical inactivity and co-existing conditions negatively affect survival outcomes. Additionally, the presence of heart failure, diabetes, and hypertension in COPD patients is linked to heightened systemic inflammation, suggesting metabolic abnormalities may contribute to disease mechanisms (14-16).

Patients with COPD who have an elevated BMI are more likely to develop MetS, a cluster of conditions that includes abdominal obesity, insulin resistance, dyslipidemia, and hypertension (17). These metabolic disturbances contribute to a heightened risk of cardiovascular disease, which is already a major cause of morbidity and mortality in COPD populations (18). The presence of excess adipose tissue, particularly visceral fat, may exacerbate systemic inflammation and oxidative stress, further promoting insulin resistance and abnormal lipid profiles (19, 20). Consequently, the combination of COPD and MetS poses a significant challenge in clinical management and underscores the need for early screening and targeted interventions to reduce cardiovascular risk in this subgroup of patients (21, 22).

MATERIALS AND METHODS

This prospective study was conducted at the Clinical Rehabilitation Hospital in Iași and included 100 patients diagnosed with COPD. The study was carried out between January 2022 and June 2023. The diagnosis of COPD was established by spirometry, based on a post-bronchodilator forced expiratory volume in one second (FEV1)/ forced vital capacity (FVC) < 0.70. Patients aged over 35 years who provided written informed consent were enrolled. Exclusion criteria included advanced renal or hepatic failure, neurological or psychiatric disorders, malignancies, and refusal to sign the informed consent form. All participants underwent comprehensive clinical and laboratory evaluations, with particular emphasis on analyzing the impact of BMI on pulmonary function. This study aimed to assess the relationship between BMI, MetS, and clinical outcomes in patients with COPD, emphasizing the importance of early nutritional monitoring as part of comprehensive disease management. Demographic data, anthropometric measure-

ments, cardiovascular risk indicators, and lung function were assessed at the baseline and again after 6 months.

Statistical Analysis. Descriptive statistics were performed using *SPSS software (version 27.0, SPSS Inc., Chicago, IL, USA)* for Windows. Data were reported as mean ± standard deviation (SD) for continuous variables or as percentages for categorical ones. The Kolmogorov-Smirnov test was applied to verify the normality of data distribution. For comparisons of continuous variables, a parametric t-test was used, while categorical variables were analyzed using Fisher`s exact test. To evaluate the strength and reliability of correlations, Pearson`s and Spearman`s (r) coefficients were employed.

Ethics. This study received ethical approval from the Research Ethics Committee of the "Grigore T. Popa" University of Medicine and Pharmacy of Iasi, Romania (Approval No. 122, dated 11th of November 2021), as well as from the Ethics Committee of the Iasi Clinical Rehabilitation Hospital on 10th of December 2021.

RESULTS

The study included 100 patients, of whom 68% were male (fig. 1). We focused on investigating BMI within the study group, highlighting an average BMI of 30.63 ± 6.842 kg/m^2 (mean ± standard deviation), with a higher value observed in subjects with COPD and MetS (32.57 ± 6.635 kg/m^2 vs. 26.68 ± 5.488 kg/m^2, p< 0.001). Moreover, 79% of the subjects had a BMI≥ 25 kg/m^2, with the majority of them being diagnosed with MetS (92.5% vs. 51.5%, p< 0.001). We also investigated abdominal circumference, and statistically significant differences were recorded between the two study groups (110.93± 13.120 vs. 99.52± 14.871, p< 0.001).

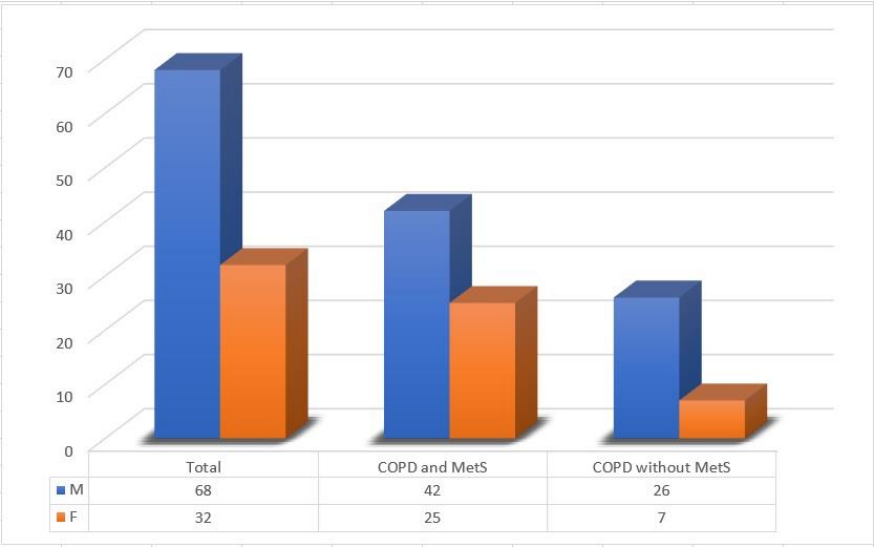

Fig. 1. Gender based distribution of COPD with and without MetS

The diagnostic criteria for MetS were analyzed by further subdividing the patients into two additional groups: those with a BMI< 25kg/m^2 and those with a

BMI≥ 25kg/m^2. The mean plasma glucose level was significantly elevated in patients with a BMI≥ 25kg/m^2 (p= 0.020). Moreover, statistically significant values were observed in the mean triglyceride levels among subjects with a BMI≥ 25kg/m^2 (p= 0.034). No statistically significant results were obtained regarding BMI, abdominal circumference, or systolic and diastolic blood pressure values (tab. I).

The patients underwent spirometric reevaluation at 6 months. At both baseline and 6- month follow-up, BMI showed a statistically significant positive correlation with FEV1 (%) and the FEV1/ FVC ratio in the total study population. These associations remained significant in the subgroup of patients with MetS, particularly for the FEV1/ FVC ratio, which demonstrated the strongest correlation (r= 0.379 at baseline and r= 0.349 at follow-up; p< 0.001). No statistically significant correlations were observed in the subgroup without MetS. Additionally, a weaker but significant correlation between BMI and FVC (%) was found at follow-up in the overall group (r= 0.223; p= 0.026) (tab. II).

The graphs illustrate the changes in BMI (fig. 2) and abdominal circumference by gender (fig. 3), between baseline and 6-month follow-up. At the initial evaluation, patients were educated on the importance of pulmonary rehabilitation programs. These programs were initiated during hospitalization and continued at home following discharge. Upon reevaluation at 6 months, both BMI and abdominal circumference showed a slight decrease in both male and female patients, reflecting a positive trend likely associated with adherence to the rehabilitation protocol.

TABLE I.

Criteria of MetS of the study population by BMI

	BMI < 25kg/m^2		**BMI ≥ 25kg/m^2**

DISCUSSION

Earlier research has suggested a link between low BMI and decreased survival in individuals with COPD (23). However, more recent data indicate that specific adverse shifts in body composition may serve as more accurate predictors of mortality than BMI alone. In people with COPD, these changes are associated with reduced exercise capacity, poorer quality of life, and a higher risk of death (4). While some studies have explored the link between body composition and disease severity, few have investigated the role of sarcopenia in relation to COPD prognosis or addressed the importance of considering sarcopenia when evaluating BMI in overweight patients to prevent diagnostic errors (24, 25).

A retrospective cohort study involving 116,463 patients with COPD showed that individuals with both low and high BMI experienced a greater number of exacerbations over the course of one year. Moreover, a low BMI was associated with the presence of pulmonary comorbidities such as interstitial lung diseases, tuberculosis, and metabolic disorders (23, 26).

A decrease in BMI has been linked to an increased risk of overall mortality, even among overweight or obese individuals with COPD (27). Epidemiological studies in cancer patients have also found that being slightly overweight or in the early stages of obesity may lead to better survival outcomes. This trend has been consistently noted in COPD populations (28). One meta-analysis of five randomized clinical trials demonstrated that a higher BMI may help preserve lung function, with the slowest decline observed in those with a BMI of 30 kg/m² or higher (29). Another meta-analysis involving over 21,000 COPD patients found that individuals who were overweight or obese had lower mortality rates than those with a normal BMI (30). These findings support the concept of the "obesity paradox," where excess weight appears to be associated with reduced risk of death (23).

Our study highlights that in COPD patients with a BMI $\geq$ 25kg/m^2, the presence of MetS is associated with significantly higher plasma glucose and triglyceride levels, compared to those without MetS. These findings suggest that elevated BMI may exacerbate metabolic disturbances in patients with COPD, reinforcing the role of excess body weight as a contributing factor to the development and progression of MetS in this population. Consequently, they emphasize the importance of routine metabolic screening and individualized therapeutic strategies in COPD patients with increased BMI. Early detection and appropriate management of MetS may improve long-term clinical outcomes, reduce cardiovascular risk, and mitigate systemic complications in this vulnerable group.

Additionally, patients with lower BMI tended to have reduced spirometric values (FEV1 and FEV1/ FVC), both at baseline and follow-up, particularly in those without MetS. This pattern may reflect the detrimental impact of low body mass in respiratory muscle strength, nutritional status, and systemic inflammation. As supported by previous literature, a lower BMI in COPD patients is often associated with a poorer prognosis, increased risk of exacerbations, hospitalization, and overall mortality. These findings underscore the importance of early nutritional assessment and interventions aimed at preventing weight loss and muscle wasting in underweight or cachectic COPD patients.

In our patients, a positive correlation was observed between BMI and spirometric parameters (FEV1, FEV1/ FVC), both at baseline and at the 6-month follow-up, particularly in those with MetS. This suggests that a higher BMI is associated with better pulmonary function in this subgroup, supporting the concept of the "obesity paradox" in COPD.

Although the obesity paradox in COPD suggests that a higher BMI may be associated with lower mortality, this phenomenon should be interpreted with caution. Factors such as body composition, the presence of malnutrition or sarcopenia, and coexisting comorbidities must be considered. Consequently, weight management in COPD patients should be individualized, avoiding

both excessive weight gain and significant weight loss in order to optimize prognosis and enhance quality of life (31-33).

Recent studies have highlighted that the protective effect of obesity in COPD may be partially attributed to the greater nutritional reserves and muscle mass that overweight patients possess, which could contribute to better tolerance of disease exacerbations and improved survival (34). Moreover, adipose tissue may exert anti-inflammatory effects through the secretion of specific adipokines, potentially modulating the chronic systemic inflammation characteristic of COPD. However, this apparent advantage should not lead to the underestimation of obesity-related risks, such as cardiovascular disease, obstructive sleep apnea, and reduced physical performance. A nuanced understanding of the obesity paradox is necessary to tailor clinical interventions and to balance metabolic and respiratory risks in COPD management (30, 32).

CONCLUSIONS

BMI plays a significant role in the clinical profile of COPD patients, being associated with altered spirometric parameters and increased metabolic risk. Higher BMI values, particularly in patients with MetS, were significantly correlated with impaired pulmonary function, as demonstrated by reduced FEV1 and FEV1/ FVC ratios. Monitoring and managing BMI in COPD patients is essential, as excess weight contributes to increased systemic inflammation, cardiovascular risk, and reduced respiratory efficiency. Incorporating weight control strategies and structured pulmonary rehabilitation programs may improve both respiratory function and metabolic outcomes in COPD patients with elevated BMI.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that they have no conflict of interest.

The present study received financial support from “Grigore T. Popa” University of Medicine and Pharmacy, Iasi, Romania, in the research program at the Doctoral School of the first author.

THE ROLE OF ROUTINE CARDIAC AND HEMATOLOGIC BIOMARKERS IN FORECASTING POSTOPERATIVE RECOVERY AND LENGTH OF STAY (Abstract): Perioperative morbidity remains a challenge in elderly orthopedic patients, particularly in the presence of cardiovascular comorbidities. Easily available biomarkers may provide prognostic value for postoperative recovery and length of hospitalization. **Aim**: To investigate the prognostic significance of cardiac and inflammatory biomarkers, including CK-MB, fibrinogen, red blood cell distribution width (RDW), and hemoglobin, on postoperative outcomes, with a focus on length of hospital stay. **Materials and methods:** We retrospectively analyzed 85 patients undergoing orthopedic surgery. Demographic, clinical, and laboratory data were collected pre- and postoperatively. Primary outcome was length of hospitalization. Associations between biomarkers and hospitalization were evaluated using Spearman correlations, group comparisons (median and quartile splits), and multivariable regression with robust standard errors. **Results:** The cohort had a mean age of 72.2 years, with equal sex distribution. Significant positive correlations were found between hospitalization days and preoperative CK-MB ($\rho = 0.286$, $p = 0.008$), postoperative CK-MB ($\rho = 0.277$, $p = 0.010$), preoperative fibrinogen ($\rho = 0.334$, $p = 0.002$), and preoperative RDW ($\rho = 0.257$, $p = 0.018$). In multivariable regression, postoperative CK-MB ($\beta = 0.190$, $p = 0.079$) and postoperative fibrinogen ($\beta = 0.115$, $p = 0.242$) emerged as the strongest predictors, though statistical significance was not reached. Variance inflation factors revealed substantial collinearity, particularly for RDW. **Conclusions:** Routine biomarkers such as CK-MB, fibrinogen, and RDW demonstrate prognostic associations with hospitalization duration in orthopedic surgery. These markers reflect myocardial stress, systemic inflammation, and hematologic resilience, respectively. Incorporating them into perioperative assessment may improve risk stratification and guide targeted management. Larger prospective studies with high-sensitivity troponin and composite indices are warranted. **Keywords:** CARDIAC BIOMARKERS, CK-MB, FIBRINOGEN, RED BLOOD CELL DISTRIBUTION WIDTH (RDW), POSTOPERATIVE OUTCOMES, HOSPITALIZATION LENGTH, RISK STRATIFICATION.

INTRODUCTION

Perioperative morbidity and mortality remain major concerns in surgical populations, particularly among elderly patients

with cardiovascular comorbidities. Accurate risk stratification and early identification of patients at higher risk for complications are critical to optimize surgical planning, anticipate adverse events, and guide perioperative management strategies. In recent years, biochemical and hematological biomarkers have gained considerable interest as potential tools for predicting short- and long-term outcomes (1).

Among these, creatine kinase MB isoenzyme (CK-MB) has been traditionally used as a marker of myocardial injury. While cardiac troponins have largely replaced CK-MB in the diagnosis of acute myocardial infarction, evidence suggests that postoperative CK-MB elevation, even within modest ranges, independently predicts mortality and adverse cardiac events following major non-cardiac surgery (1). This highlights its potential role as a valuable prognostic indicator in the perioperative context, particularly in elderly patients undergoing orthopedic procedures who frequently harbor silent or subclinical cardiovascular disease.

Red blood cell distribution width (RDW), a routinely available parameter reflecting anisocytosis, has emerged as a powerful prognostic biomarker across various clinical settings. Elevated RDW levels have been linked to increased mortality, arrhythmias, and renal dysfunction in patients undergoing cardiac surgery (2). Furthermore, in non-cardiac surgical cohorts, higher preoperative RDW has been associated with more than a twofold increase in 30-day postoperative mortality, suggesting it may reflect underlying chronic inflammation, nutritional deficiencies, and impaired erythropoiesis that collectively worsen recovery potential (3).

In parallel, fibrinogen, a key coagulation factor and acute phase reactant, has demonstrated prognostic utility in surgical patients. Hypofibrinogenemia following cardiac surgery independently predicts excessive postoperative bleeding and the need for transfusion (4). A meta-analysis confirmed that both pre- and postoperative fibrinogen concentrations inversely correlate with blood loss, reinforcing its role as a determinant of perioperative hemostasis and recovery (5). In orthopedic surgery, where perioperative bleeding and transfusion requirements significantly affect morbidity, fibrinogen dynamics may hold particular prognostic value.

Collectively, these biomarkers represent distinct yet complementary aspects of postoperative physiology: CK-MB as an indicator of myocardial stress or injury, RDW as a marker of systemic resilience and chronic disease burden, and fibrinogen as a determinant of coagulation and inflammatory status. Their combined evaluation may provide a multidimensional assessment of perioperative risk, enabling better prediction of outcomes such as prolonged hospitalization, postoperative complications, and recovery trajectories.

The present study **aims** to evaluate the prognostic value of CK-MB, fibrinogen, RDW, and related biomarkers in patients undergoing orthopedic surgery. By integrating these routinely measured parameters into perioperative risk assessment, clinicians may be able to refine patient stratification and optimize perioperative care (3).

MATERIALS AND METHODS

Study Design and Population. This was a retrospective observational study conducted on patients admitted for orthopedic surgery, primarily hip fracture repair

and prosthetic joint replacement, between (insert years, e.g., January 2018 and December 2023). The study cohort consisted of consecutive patients with complete clinical, laboratory, and surgical records available for analysis. Patients with incomplete datasets or missing postoperative biomarker measurements were excluded.

Data Collection. Demographic and clinical variables were extracted from medical records, including sex, age, primary diagnosis, and relevant comorbidities such as arterial hypertension, pulmonary hypertension, ischemic heart disease, chronic kidney disease, diabetes mellitus, and chronic liver disease.

Laboratory biomarkers were collected both preoperatively and postoperatively. The primary biomarkers of interest were:

- Creatine kinase MB isoenzyme (CK-MB), measured in U/L.
- Fibrinogen, measured in mg/dL.
- Red blood cell distribution width (RDW), expressed as a percentage.
- Hemoglobin, measured in g/dL.

Additional markers, including INR, APTT, creatinine, and electrolytes, were also recorded.

Surgical data included day of intervention (relative to admission), type of prosthesis, and perioperative transfusion requirements.

Outcomes. The primary outcome was length of hospitalization (days). Secondary outcomes included:

- Postoperative complications, defined as cardiac (arrhythmia, myocardial injury, heart failure) or non-cardiac (infection, bleeding requiring transfusion).
- Biomarker variation (preoperative vs. postoperative changes) and their association with outcomes.

Statistical Analysis. All statistical analyses were performed using Python (version 3.11) within the Visual Studio Code environment. The following Python libraries were employed: pandas (v.2.1.0) for data management and preprocessing, numpy (v.1.26.0) for numerical operations, scipy.stats (v.1.11.0) for correlation analyses and hypothesis testing (Shapiro-Wilk normality test, Spearman and Pearson correlation coefficients, Mann-Whitney U test, independent-samples t-test, Kruskal-Wallis test, and ANOVA), stats models (v.0.14.0) for regression modeling, including ordinary least squares (OLS) regression with robust (HC3) standard errors, multivariable linear regression, and logistic regression, matplotlib (v.3.8.0) and seaborn (v.0.13.0) for the creation of plots and data visualizations, pingouin (v.0.5.3) for effect size estimation and variance inflation factor (VIF) analysis to evaluate multicollinearity.

Continuous variables were assessed for distributional normality using the Shapiro-Wilk test and reported as mean ± standard deviation (SD) when normally distributed or as median with interquartile range (IQR) otherwise. Categorical variables were summarized as frequencies and percentages.

Associations between biomarkers and hospitalization duration were evaluated using Pearson's correlation for normally distributed variables and Spearman's rank correlation otherwise. Group comparisons were conducted using independent-samples t-tests or Mann-Whitney U tests, depending on data distribution. For comparisons across multiple groups, ANOVA or Kruskal-Wallis tests were employed.

Multivariable regression analyses were performed to identify independent predictors of hospitalization duration. Variables with $p < 0.10$ in univariate analyses were considered for entry into the multivariable

models. Variance inflation factors were computed to assess multicollinearity. Logistic regression models were additionally used to explore associations between biomarker levels and the occurrence of postoperative complications.

Ethical Considerations. The study was conducted in accordance with the Declaration of Helsinki. Approval was obtained from the institutional ethics committee. As this was a retrospective analysis of anonymized data, informed consent was waived.

RESULTS

A total of 85 patients were included in the final analysis. The mean age of the cohort was 72.2 years, with an equal sex distribution (50% female, 50% male). The majority were admitted for hip fracture repair with prosthesis implantation. Baseline biomarker levels and hospitalization duration are summarized in first table. The median hospitalization length was 10 days (IQR: 7-14).

Spearman correlation analysis revealed that several biomarkers were significantly associated with hospitalization duration. Higher preoperative CK-MB ($\rho = 0.286$, $p = 0.008$), postoperative CK-MB ($\rho = 0.277$, $p = 0.010$), preoperative fibrinogen ($\rho = 0.334$, $p = 0.002$), and preoperative RDW ($\rho = 0.257$, $p = 0.018$) were each correlated with prolonged hospitalization. In contrast, postoperative fibrinogen and postoperative RDW showed weaker, non-significant associations. Complete correlation coefficients are reported in Table II.

TABLE I.

Descriptive statistics of pre- and postoperative biomarkers and hospitalization days.

	Count	Mean	Std. dev.	Min.	25%	50%	Median	75%	Max.

Hb post-op	85	0.028	0.7965

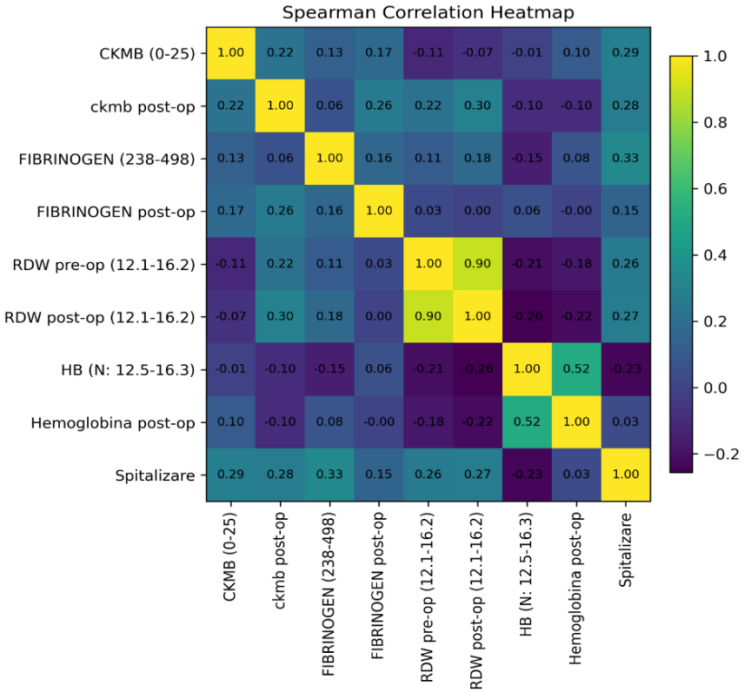

Fig. 1. Heatmap of Spearman correlations between biomarkers and hospitalization days.

The overall correlation structure between biomarkers and hospitalization is illustrated in first figure, where positive associations are evident for CK-MB, fibrinogen, and RDW.

Group Comparisons

When stratified by median values, patients with higher biomarker levels (≥ median) consistently demonstrated longer hospital stays compared to those below the median. This difference was most pronounced for preoperative fibrinogen and RDW (fig. 2).

Quartile-based analyses further highlighted a stepwise increase in hospitalization with rising biomarker levels. Patients in the highest quartile (Q4) of fibrinogen and RDW had the longest hospital stays, compared with those in the lowest quartile (Q1) (fig. 3).

Multivariate Regression Analysis

In the multivariable regression model including all biomarkers simultaneously, postoperative CK-MB (standardized $\beta = 0.190$, $p = 0.079$) and postoperative fibrinogen ($\beta = 0.115$, $p = 0.242$) emerged as the strongest predictors of hospitalization length, although statistical significance was not achieved. Preoperative CK-MB and RDW lost significance after adjustment, suggesting overlapping predictive domains. Full regression results are provided in Table III and standardized coefficients in Table IV.

A graphical summary of standardized coefficients with 95% confidence intervals is provided in fig. 4, highlighting the relative contribution of CK-MB and fibrinogen to hospitalization outcomes.

Multicollinearity Diagnostics

Variance inflation factor (VIF) analysis revealed substantial collinearity among some predictors, particularly RDW (VIF ≈ 102) and fibrinogen (VIF ≈ 9.3), indicating that results involving these variables should be interpreted with caution (tab. V).

TABLE V.

Variance inflation factors for included predictors.

Predictor	VIF

RDW post-op (12.1-16.2)	94.245
Hb (n: 12.5-16.3)	60.146
Hb post-op	60.586

DISCUSSION

In this single-center cohort of older adults undergoing orthopedic surgery, we found that higher preoperative CK-MB, postoperative CK-MB, preoperative fibrinogen, and preoperative RDW correlated with longer hospital stay, whereas in multivariable analysis the postoperative CK-MB and postoperative fibrinogen showed the largest (albeit non-significant) adjusted effects. These findings align with the broader perioperative evidence that myocardial injury after non-cardiac surgery (MINS) and systemic inflammatory/coagulation signals track with worse short-term recovery and resource use, including length of stay (LOS). Our data, centered on routinely measured biomarkers, support the concept of a multidomain biological signal, myocardial stress (CK-MB), inflammatory/hemostatic tone (fibrinogen), and hematologic reserve/inflammation (RDW), that together shape postoperative trajectories (6-8).

Extensive literature shows that postoperative cardiac biomarker elevations (classically CK-MB and now predominantly troponin) are associated with adverse outcomes after non-cardiac surgery. In the landmark work by Landesberg *et al.*, even low-level postoperative CK-MB and troponin elevations independently predicted long-term mortality after major vascular surgery, highlighting their complementary prognostic value (1). Contemporary analyses of MINS consistently link postoperative troponin rises to higher short-term mortality and complications, and several cohorts also report longer hospital stays among patients with myocardial injury (7, 9, 10). Our observation that postoperative CK-MB exerted the strongest adjusted effect on LOS is therefore directionally concordant with the troponin-centric literature, even if CK-MB is a legacy assay; the mechanistic plausibility is that subclinical myocardial injury drives hemodynamic instability, arrhythmias, or non-cardiac organ dysfunction that prolongs recovery (1, 7, 9, 10).

Preoperative RDW has emerged as a robust, low-cost prognostic marker across surgical populations. Large studies demonstrate associations between higher RDW

and postoperative mortality in non-cardiac surgery (3, 11, 12), and in hip-fracture cohorts RDW predicts mortality as well (13). Importantly for our endpoint, RDW has also been linked to prolonged ICU and hospital LOS among critically ill fracture patients, dovetailing with our univariable correlations (14). RDW likely integrates chronic inflammation, iron/folate deficiency, renal function, and marrow stress, all of which impair physiologic reserve. In our multivariable model, the RDW signal attenuated, possibly reflecting multicollinearity with other inflammatory and hematologic variables (consistent with our high VIFs) and/or residual confounding by anemia or frailty (11, 12, 14, 15).

Fibrinogen is pivotal for clot firmness and is an acute-phase reactant. In orthopedic and spine surgery, lower preoperative fibrinogen has been associated with higher bleeding/transfusion needs (spine) (16), though findings are mixed in arthroplasty, where a 2023 study reported no association between preoperative fibrinogen and transfusion in THA (17). Interventional evidence suggests fibrinogen concentrate can reduce perioperative blood loss and transfusion in THA (18), reinforcing the biological relevance of fibrinogen to operative hemostasis. Beyond bleeding, higher preoperative inflammatory tone reflected by fibrinogen (or composite indices such as the fibrinogen/albumin ratio, FAR) has been linked to longer hospital and ICU LOS and greater morbidity in vascular disease and hip-fracture cohorts, mirroring our positive correlation between preoperative fibrinogen and LOS (13, 19). Taken together, our results likely capture two overlapping phenomena: (i) hemostatic sufficiency that reduces bleeding-related delays and (ii) systemic inflammation that prolongs convalescence (13, 16, 17, 19).

First, while CK-MB highlighted risk in our data, postoperative troponin monitoring is better validated and should be preferred where available; routine surveillance in higher-risk patients identifies those at risk for complications and longer LOS, enabling targeted monitoring and cardioprotective strategies (8, 9). Second, RDW can be integrated into preoperative assessment as a readily available marker of physiologic reserve; when elevated, it should prompt evaluation of reversible contributors (iron deficiency, malnutrition, renal dysfunction). Third, fibrinogen merits dual consideration, as a modifiable hemostatic variable (with goal-directed therapy when low) and as an inflammatory proxy when high; however, its relationship to LOS in arthroplasty appears context-dependent, warranting individualized interpretation and, where appropriate, adjunct measures (e.g., TXA protocols, blood management pathways) (7, 9, 10, 13, 14, 17).

Our study is retrospective, single-center, and modest in size, which limits power, particularly for multivariable inference where collinearity was substantial (e.g., RDW). We focused on LOS rather than adjudicated complications; while LOS is clinically meaningful, it is influenced by non-medical factors (bed management, rehabilitation logistics). Biomarker timing was limited to available clinical draws; serial measurements, especially of high-sensitivity troponin, could refine prognostication. Future multicenter studies should test parsimonious models that combine postoperative troponin with RDW and fibrinogen (or composite indices like FAR), and evaluate whether targeted interventions (anemia correction, anti-inflammatory strategies, fibrinogen-guided hemostasis, cardioprotective

pathways) can shorten LOS and improve recovery (1, 6, 7, 13, 14, 18).

CONCLUSIONS

In this retrospective study of patients undergoing orthopedic surgery, we found that preoperative CK-MB, fibrinogen, and RDW, as well as postoperative CK-MB, were significantly associated with prolonged hospitalization. Although the strength of association diminished after multivariable adjustment, postoperative CK-MB and fibrinogen remained the most consistent predictors of length of stay, underscoring the prognostic value of cardiac and inflammatory biomarkers in the perioperative setting.

These findings support the integration of routine laboratory parameters, including CK-MB, RDW, and fibrinogen, into perioperative risk stratification frameworks. They highlight the interplay between myocardial stress, hematologic resilience, and inflammatory/hemostatic balance in shaping recovery trajectories after major orthopedic procedures.

Future research should validate these results in larger, prospective, multicenter cohorts, ideally incorporating high-sensitivity troponins and composite indices such as the fibrinogen/albumin ratio. Interventional trials exploring the correction of modifiable factors, such as anemia, nutritional deficits, or hypofibrinogenemia, may further determine whether biomarker-guided perioperative strategies can shorten hospital stay and improve outcomes in this vulnerable population.

CONFLICT OF INTERESTS AND FUNDING

The authors declare no conflict of interests. The research did not receive external funding.

DISTINCT METABOLIC AND STONE COMPOSITION PATTERNS IN FIRST EPISODE AND RECURRENT UROLITHIASIS PATIENTS (Abstract): The objective of this study was to identify clinical, metabolic, and compositional factors associated with stone recurrence, using morpho-spectroscopic stone analysis combined with biochemical and dietary assessment. **Materials and methods:** We retrospectively analyzed 1,380 patients with urinary lithiasis evaluated at the Michel Daudon Morphological and Spectroscopic Analysis Center, Iași, Romania, between 2018 and 2022. Patients were divided into first-episode (n=842) and recurrent (n=538) groups. Demographic data, metabolic profile, dietary habits, and stone composition were assessed. Multivariable logistic regression was used to identify independent predictors of recurrence. **Results:** Recurrent patients accounted for 39.1% of the cohort and were significantly older. Calcium oxalate monohydrate and dihydrate stones predominated in first episodes, whereas uric acid, urate-mixed, and struvite calculi were more frequent in recurrent cases. Obesity, hyperuricemia, hypertension, type 2 diabetes, and chronic kidney disease were significantly more prevalent among recurrent stone formers. Dietary assessment showed that low fruit and vegetable intake and high sodium consumption were strongly associated with recurrence. Logistic regression identified hyperuricemia (OR=2.3), obesity (OR=1.9), hypertension (OR=1.5), and chronic kidney disease (OR=1.6) as independent predictors. **Conclusions**: Stone recurrence is characterized by a distinct clinical and metabolic profile, compositional shifts toward uric acid and struvite calculi, and unfavorable dietary habits. These findings confirm the systemic nature of lithiasis and support the integration of morpho-spectroscopic, metabolic, and nutritional evaluation into standard urological practice. **Keywords:** URINARY STONE DISEASE, RECURRENCE, MORPHO-SPECTROSCOPIC ANALYSIS, METABOLIC SYNDROME, URIC ACID, PREVENTION.

INTRODUCTION

Urinary stone disease represents a major and growing public health challenge worldwide. Its lifetime prevalence is estimated between 10-12% in Europe and North America, with increasing incidence also reported in developing countries (1). The disease is highly recurrent: more than 50% of patients are expected to develop a new episode within 10 years after the first event. Beyond the acute burden of renal colic and the need for surgical or endourological interventions, recurrence is associated with progressive renal impair-

ment, reduced quality of life, and considerable healthcare costs (1, 2).

The etiology of urinary stone disease is multifactorial. Established risk factors include metabolic abnormalities such as obesity, hypertension, diabetes mellitus, dyslipidemia, and hyperuricemia, which are frequently clustered in the metabolic syndrome (3, 4). Dietary habits strongly modulate lithogenic risk: high sodium intake and an elevated sodium-to-potassium ratio significantly increase stone risk, whereas diets rich in potassium, fruits, and vegetables are protective (5). High intake of animal protein and oxalate-rich foods contributes to uric acid and calcium oxalate stones, respectively (6, 7). Lifestyle patterns also play a role: sedentary behavior increases risk, while vigorous physical activity has been shown to mitigate it (1, 8).

Epidemiological data reveal changing demographic trends. Traditionally, stone disease was more common in men; however, recent reports suggest a narrowing gender gap, with increasing incidence among women and even among adolescents. Moreover, disparities have been reported across ethnic and socioeconomic groups, with disproportionate increases among Black and Hispanic populations in the United States and with variable access to metabolic evaluation and surgical care (4). Such observations underline the systemic and societal dimensions of stone disease beyond its local urological manifestations.

Pathophysiological mechanisms of stone formation are closely linked to morphological and compositional features. Randall's plaques, intratubular crystallization, and papillary erosions represent distinct initiating pathways, each associated with specific stone types. Comprehensive morpho-constitutional analysis, as proposed by Daudon and colleagues, combines macroscopic morphology with infrared spectroscopy to provide insights into the mechanisms of stone genesis and recurrence. Stone composition also predicts clinical behavior: calcium oxalate monohydrate and dihydrate stones are usually small and more likely to pass spontaneously, whereas struvite, brushite, and cystine stones tend to be larger and associated with higher recurrence rates. Furthermore, metabolic conditions influence stone type: uric acid stones are strongly associated with obesity, diabetes, and insulin resistance, while calcium phosphate and brushite stones are linked to hypercalciuria and hyperparathyroidism (1, 3, 9–11).

In Romania, recent studies have highlighted the interplay between stone composition, metabolic comorbidities, and dietary risk factors, with hypertension associated with calcium oxalate monohydrate, diabetes with uric acid stones, obesity with calcium oxalate dihydrate, and specific dietary habits predisposing to urate and oxalate lithiasis. Such findings support the need for an integrated clinical, metabolic, and morpho-spectroscopic approach in the evaluation of stone formers(11-14).

Despite these advances, few studies have directly compared the metabolic and morpho-spectroscopic profiles of patients at their first stone episode versus those with documented recurrence. Given the clinical and economic impact of recurrent stones, identifying compositional shifts and associated metabolic abnormalities is crucial for guiding preventive strategies.

The aim of our study was to compare the clinic-biological metabolic profile and morpho-spectroscopic characteristics of urinary stones between patients presenting with a first episode and those with recurrence. By integrating morphological classification, infrared spectroscopic analysis,

and metabolic assessment, we sought to elucidate the factors driving recurrence and to highlight potential targets for prevention.

MATERIALS AND METHODS

Study design and setting. We conducted a retrospective, observational study at the Urology Clinic of "Dr. C. I. Parhon" Clinical Hospital, Iași, Romania, in collaboration with the Michel Daudon Morphological and Spectroscopic Analysis Center. The study covered the period from January 2018 to June 2025. All patients underwent standard evaluation and treatment for urinary stone disease according to current urological guidelines.

Study population. During the study period, 1,520 patients diagnosed with urinary lithiasis were evaluated. For each patient, only a single stone specimen was analyzed, either collected spontaneously or retrieved during surgical/endourological procedures. After exclusion of incomplete or fragmented samples, a total of 1,380 stones were available for analysis. Patients were categorized into two groups.

Clinical and anthropometric evaluation. All patients underwent standardized clinical examination including measurement of body mass index (BMI), waist circumference, and blood pressure. Relevant comorbidities such as type 2 diabetes mellitus, hypertension, dyslipidemia, hyperuricemia, and chronic kidney disease (CKD) were recorded based on clinical history and laboratory data.

Stone analysis. Macroscopic morphological assessment of calculi was performed according to the Daudon classification, documenting external surface, section, and crystalline organization. Infrared spectroscopy (FTIR) was used for compositional analysis, enabling precise identification of crystalline phases (e.g., calcium oxalate monohydrate, calcium oxalate dihydrate, uric acid, urates, carbapatite, struvite, cystine, protein matrix). Each stone was assigned a morpho-constitutional type based on combined macroscopic and spectroscopic findings.

Dietary evaluation. Patients completed a standardized dietary questionnaire developed in our department, focusing on the frequency and quantity of consumption of salt, animal proteins, oxalate-rich foods, dairy products, alcohol, fruits, and vegetables. Reported intake patterns were categorized as favorable or unfavorable based on established nutritional recommendations for stone prevention.

Statistical analysis. Continuous variables were expressed as mean ± standard deviation (SD). Categorical variables were presented as absolute numbers and percentages. Comparisons between groups (first episode *vs.* recurrence) were performed using Student's t-test or Mann–Whitney U test for continuous variables and χ^2 or Fisher's exact test for categorical variables. A p-value <0.05 was considered statistically significant. Statistical analysis was performed using *SPSS v. 26* (IBM Corp., Armonk, NY, USA).

All patients signed informed consent forms prior to participation. The study protocol was reviewed and approved by the Research Ethics Board of the "Dr. C. I. Parhon" Clinical Hospital, Iași, Romania (approval no. 18/08.03.2022).

RESULTS

A total of 1,380 patients were included in the analysis. Of these, 842 (60.9%) presented with a first episode of urolithiasis, while 538 (39.1%) had a history of recurrence.

The overall mean age was 52.8 ± 13.4 years (range 18-79), with a male-to-female ratio of 1.4: 1. Patients with recurrence were older on average than first-episode patients (55.1 ± 12.9 *vs.* 51.2 ± 13.7 years, p=0.01).

TABLE I.

Demographic characteristics of the study population

Variable	First episode (n=842)	Recurrence (n=538)	Total (n=1,380)
Age, years (mean ± SD)	51.2 ± 13.7	55.1 ± 12.9	52.8 ± 13.4
Age range (years)	18–77	20–79	18–79
Male sex, n (%)	498 (59.1%)	333 (61.9%)	831 (60.2%)
Female sex, n (%)	344 (40.9%)	205 (38.1%)	549 (39.8%)
Urban residence	505 (60.0%)	334 (62.1%)	839 (60.8%)
Rural residence	337 (40.0%)	204 (37.9%)	541 (39.2%)
County of residence			
Iași	547 (65.0%)	350 (65.1%)	897 (65.0%)
Suceava	84 (10.0%)	55 (10.2%)	139 (10.1%)
Botoșani	76 (9.0%)	46 (8.6%)	122 (8.8%)
Neamț	63 (7.5%)	39 (7.2%)	102 (7.4%)
Vaslui	46 (5.5%)	33 (6.1%)	79 (5.7%)
Other counties	26 (3.0%)	15 (2.8%)	41 (3.0%)

Table II summarizes the clinical and metabolic characteristics of the study population. Patients with recurrent stones were significantly older and had higher BMI compared to those with a first episode. The prevalence of abdominal obesity, hyper-uricemia, hypertriglyceridemia, hypertension, type 2 diabetes mellitus, and chronic kidney disease was markedly higher among recurrent stone formers, highlighting their more unfavorable metabolic profile.

TABLE II.

Clinical and metabolic characteristics of first-episode *vs.* recurrent patients

Parameter	First episode (n=842)	Recurrence (n=538)	p-value
Age, years (mean ± SD)	51.2 ± 13.7	55.1 ± 12.9	0.01
Male sex, n (%)	498 (59.1%)	333 (61.9%)	0.37
Female sex, n (%)	344 (40.9%)	205 (38.1%)	—
BMI, kg/m² (mean ± SD)	27.1 ± 3.9	29.3 ± 4.4	<0.001
Abdominal obesity, n (%)	176 (20.9%)	168 (31.2%)	0.003
Hyperuricemia, n (%)	159 (18.9%)	187 (34.8%)	<0.001
Hypertriglyceridemia, n (%)	126 (15.0%)	141 (26.2%)	0.002
Hypertension, n (%)	178 (21.1%)	174 (32.4%)	0.004
Type 2 diabetes, n (%)	83 (9.8%)	93 (17.3%)	0.01
CKD (eGFR <60), n (%)	27 (3.2%)	37 (6.9%)	0.03

Clinical and metabolic characteristics. Patients with recurrence displayed a more adverse metabolic profile. They had higher mean BMI and significantly higher prevalence of abdominal obesity, hyperuricemia, hypertriglyceridemia, hypertension, diabetes, and CKD compared to first-episode patients. Recurrent stone formers were older, more frequently obese, and exhibited a significantly higher burden of metabolic comorbidities than first-episode patients.

Stone composition

Calcium oxalate was the predominant stone type (59.8%), with whewellite (calcium oxalate monohydrate, COM) at 37.1% and weddellite (calcium oxalate dihydrate, COD) at 22.7%. Uric acid stones accounted for 13.9%, urate-predominant mixed forms for 13.5%, carbapatite for 8.4%, struvite for 4.1%, and rare forms (cystine/protein) for 0.3%.

Marked compositional differences were observed between groups. First-episode patients predominantly formed calcium oxalate stones (COM 43.0%, COD 24.7%), while recurrent patients more frequently had uric acid (20.4% *vs.* 9.7%, p<0.001) and urate-containing mixed calculi (17.7% *vs.* 10.8%, p=0.002). Struvite stones were also more common in recurrent cases (6.6% *vs.* 2.4%, p=0.01). Recurrent stone formers showed a significant compositional shift toward uric acid–containing, mixed, and infection-related stones compared to first-episode patients.

TABLE III.

Stone composition in first episode *vs.* recurrence

Stone type	Overall (n, %)	First episode (n=842)	Recurrence (n=538)	p-value
COM	512 (37.1%)	362 (43.0%)	150 (28.4%)	<0.001
COD	314 (22.7%)	208 (24.7%)	104 (19.3%)	0.04
Uric acid	192 (13.9%)	82 (9.7%)	110 (20.4%)	<0.001
Urates (mixed)	186 (13.5%)	91 (10.8%)	95 (17.7%)	0.002
Carbapatite	116 (8.4%)	76 (9.0%)	41 (7.6%)	0.47
Struvite	57 (4.1%)	20 (2.4%)	36 (6.6%)	0.01
Rare (Cys / protein)	4 (0.3%)	3 (0.4%)	1 (0.2%)	0.68
Total	**1,380 (100%)**	**842 (100%)**	**538 (100%)**	—

Multivariable logistic regression analysis (tab. IV) identified several independent predictors of stone recurrence. Increasing age was significantly associated with higher odds of recurrence, with an adjusted OR of 1.18 per decade (95% CI 1.06–1.31, p=0.002). Among metabolic factors, obesity (BMI ≥30 kg/m²) nearly doubled the risk (OR=1.90, p<0.001), while hyperuricemia emerged as the strongest predictor, conferring more than a two-fold increased risk (OR=2.30, p<0.001). Hypertension (OR=1.50, p=0.012) and chronic kidney disease (OR=1.62, p=0.041) also remained significant after adjustment. From a dietary perspective, low fruit and vegetable consumption (OR=1.80, p=0.001) and high sodium intake (OR=1.42, p=0.023) were associated with recurrence, underlining the role of lifestyle factors. In contrast, sex, urban/rural residence, and alcohol intake were not independent predictors in the adjusted model. Overall, the model showed good discrimination (AUC=0.77), explaining approximately 22% of the variance in recurrence risk.

TABLE IV.

Multivariable logistic regression identifying independent predictors of recurrence

Predictor (reference)	Adjusted OR	95% CI	p-value
Age (per 10 years)	1.18	1.06–1.31	0.002
Male sex (female)	1.12	0.90–1.38	0.31
BMI ≥30 kg/m² (<30)	1.90	1.40–2.60	<0.001
Hyperuricemia (no)	2.30	1.70–3.10	<0.001
Hypertension (no)	1.50	1.10–2.00	0.012
Type 2 diabetes (no)	1.35	0.98–1.86	0.065
Hypertriglyceridemia (no)	1.28	0.96–1.70	0.089
CKD, eGFR <60 (no)	1.62	1.02–2.57	0.041
Low fruit/vegetable intake (no)	1.80	1.30–2.50	0.001
High sodium intake (no)	1.42	1.05–1.92	0.023
Frequent alcohol intake (no)	1.36	0.98–1.90	0.064
Urban residence (rural)	1.10	0.86–1.40	0.44

DISCUSSION

This study, performed in a large cohort of patients managed at the Michel Daudon Morphological and Spectroscopic Analysis Center, Iași, analyzed in detail the clinical, metabolic, and compositional differences between first episode and recurrent stone formers. The results demonstrate that recurrence is associated with older age, greater metabolic burden, specific dietary patterns, and a compositional shift toward uric acid-containing and struvite stones.

Recurrent cases represented nearly 40% of the cohort, a proportion comparable to the recurrence rates reported internationally, where up to half of patients develop a new episode within 10 years. Age was a significant determinant, with recurrent patients being older than those with a first episode. Similar observations were made in large European cohorts, where increasing age correlated with larger stones and lower likelihood of spontaneous passage. The male predominance persisted in our series (60.2%), which is in line with the traditional epidemiology of lithiasis, though other reports indicate a narrowing of the gender gap in Western countries(15, 16). The geographic distribution, with two-thirds of patients originating from Iași county, reflects the tertiary referral profile of our center and is consistent with regional clustering of lithiasis observed in Romanian populations (3, 17).

Morpho-spectroscopic analysis identified significant compositional differences between groups. COM and COD were more frequent in first-episode patients, whereas uric acid, urate-mixed, and struvite calculi were characteristic of recurrence. Such patterns are in line with the morpho-constitutional classification proposed by Daudon, which links uric acid and infection-related stones to systemic

and recurrent disease(4, 16).

Regional studies also documented correlations between comorbidities and stone type: hypertension was associated with COM, diabetes with uric acid, and obesity with COD (3,18). These data support the concept that recurrent lithiasis reflects not only anatomical predisposition but also persistent metabolic or infectious drivers.

Recurrent patients exhibited a significantly higher prevalence of obesity, hyperuricemia, hypertension, diabetes, and chronic kidney disease. These findings are concordant with large-scale studies that identified the metabolic syndrome as a major contributor to stone disease (16). In our cohort, hyperuricemia conferred the highest independent risk for recurrence, followed by obesity, hypertension, and CKD. These results are consistent with analyses of metabolically active lithiasis in Romanian populations, where clustering of biochemical disturbances was shown to increase recurrence risk. The association of metabolic abnormalities with recurrence strengthens the interpretation of urinary stone disease as a systemic disorder with renal, vascular, and metabolic implications (19, 20).

Dietary imbalance emerged as an additional determinant of recurrence. Patients with low intake of fruits and vegetables and high sodium consumption were significantly more likely to develop recurrent stones. This finding is supported by nutritional studies indicating that the sodium-to-potassium ratio is a reliable predictor of stone risk, with potassium-rich diets exerting a protective effect (21). Local observations also showed that obese stone formers often fail to adhere to dietary recommendations, which may explain the persistence of lithiasis despite medical advice (3, 22). Alcohol intake was more common in recurrent patients but did not remain significant in adjusted models, a result consistent with studies reporting no clear dose–response relationship between alcohol and stone risk. Recent evidence also suggests that beyond sodium and potassium balance, other dietary components exert significant influence on stone recurrence. High animal protein intake increases acid load, enhances urinary calcium and uric acid excretion, and reduces urinary citrate, thereby favoring both uric acid and calcium oxalate lithiasis (5). Conversely, plant-based proteins and diets rich in alkali-producing foods may offer protective effects. Fructose-containing sweetened beverages have been associated with increased uric acid production and recurrent lithiasis in several cohorts, while inadequate fluid intake remains a major risk factor, particularly in rural populations with limited access to structured dietary counselling. Emerging studies also highlight the role of gut microbiota, showing that reduced colonization with *Oxalobacter formigenes* diminishes intestinal oxalate degradation, thereby contributing to calcium oxalate stone formation (1, 7, 23). These aspects underline that recurrence is not only the result of isolated dietary imbalances but of broader lifestyle and environmental patterns that warrant multifaceted preventive interventions. Sedentary lifestyle, although not directly assessed in this cohort, has been linked elsewhere to increased risk of lithiasis (20, 21).

Stone composition has direct clinical

relevance for urological management. Clinical experience in Romanian series demonstrated that COM calculi are more resistant to ESWL compared to other types. Comparative evaluations of electrohydraulic and electromagnetic lithotripters confirmed that stone composition remains a critical determinant of fragmentation success, regardless of technology (24-26). These results provide context for the present findings, where recurrent patients more frequently presented with uric acid and struvite stones-calculi known for therapeutic difficulty and for requiring adjuvant medical or anti-infective strategies.

Several large-scale analyses have demonstrated that calcium oxalate monohydrate calculi, while frequent in first-episode cases, are often linked to lower recurrence rates compared with uric acid or struvite stones (27). The latter are frequently associated with systemic conditions such as metabolic syndrome, diabetes, or chronic infection, which perpetuate the lithogenic milieu and favor multiple episodes (16, 21, 28). Uric acid stones have been correlated with obesity, insulin resistance, and acidic urinary pH, supporting their role as markers of metabolic imbalance rather than isolated events (29-31).

The cumulative evidence demonstrates that stone recurrence is not a random phenomenon but the clinical expression of systemic derangements combining metabolic, dietary, and infectious factors. International data have also linked stone disease to accelerated chronic kidney disease progression and to disparities in access to metabolic evaluation (26, 32). Within this framework, the systematic use of morpho-spectroscopic analysis, as applied in our center, enables the identification of high-risk phenotypes and the implementation of tailored preventive interventions.

The strengths of this study include the large patient cohort, the systematic application of morpho-spectroscopic analysis in a specialized reference center, and the integration of dietary, metabolic, and clinical data. Limitations stem from its retrospective design and single-center setting, although the referral nature of our institution provides regional representativeness. Prospective, multicenter investigations are warranted to confirm these findings and to assess the effectiveness of targeted preventive strategies.

CONCLUSIONS

Stone recurrence reflects a specific pathophysiological profile characterized by adverse metabolic conditions, unfavorable dietary patterns, and a compositional shift toward uric acid and struvite calculi. Recognition of these determinants emphasizes the systemic nature of lithiasis and establishes morpho-spectroscopic analysis, combined with metabolic and nutritional evaluation, as essential tools for accurate risk stratification and the design of effective preventive strategies.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

HEMOGLOBIN A1C AND BODY MASS INDEX AS PREDICTORS OF DISCREPANCIES BETWEEN CONTINUOUS GLUCOSE MONITORING AND GLUCOMETER READINGS IN PREGNANT WOMEN WITH GESTATIONAL DIABETES (Abstract): This study investigated the relationship between differences in continuous glucose monitoring (CGM) and glucometer measurements and the clinical factors hemoglobin A1c (HbA1c) and body mass index (BMI) in women with gestational diabetes. We also evaluated if HbA1c and BMI could serve as predictors of CGM-glucometer differences. **Materials and methods**: HbA1c was measured both continuously and categorically (≥5.9% vs <5.9%), and BMI was calculated in kg/m². An independent-samples t-test compared CGM differences between the two HbA1c categories. Pearson correlations examined relationships between CGM differences and HbA1c and BMI. A multiple linear regression assessed whether HbA1c and BMI predicted CGM differences. **Results**: Patients with elevated HbA1c (≥5.9%) had significantly higher CGM differences ($M = 28.71$, $SD = 0.73$) compared to those with lower HbA1c ($M = 23.17$, $SD = 0.91$), $t(42) = -19.94$, $p < 0.001$. CGM differences were very strongly correlated with HbA1c ($r = .996$, $p < 0.001$) and BMI ($r = .984$, $p < 0.001$). In the multiple regression model, only HbA1c significantly predicted CGM differences ($B = 26.52$, $SE = 2.18$, $p < 0.001$), whereas BMI was not statistically significant. The model explained 99.3% of the variance in CGM differences ($R^2 = 0.993$). **Conclusions.** The findings of our study suggest that HbA1c is strongly associated with CGM-glucometer differences, while BMI, despite a strong correlation, does not independently predict discrepancies when HbA1c is considered. These results underscore the importance of HbA1c in assessing CGM accuracy. **Keywords:** HEMO-GLOBIN, BODY MASS INDEX, PREDICTORS, CONTINUOUS GLUCOSE MONITORING, PREGNANT WOMEN, GESTATIONAL DIABETES.

INTRODUCTION

Continuous glucose monitoring (CGM) has become an increasingly important tool for measuring glycemic control, particularly in populations at risk for glucose abnormalities such as women with gestational diabetes (1). CGM offers frequent glucose readings over time, which can reveal fluctuations that are not captured by traditional glucometer measurements (2). However, discrepancies between CGM and glucometer readings, particularly in the context of gestational diabetes, have been understudied, and investigating the factors that contribute to these differences may be critical for clinical interpretation.

Hemoglobin A1c (HbA1c) is a form of hemoglobin with glucose bound to it (3). Since red blood cells have a lifespan of approximately three months, HbA1c can provide an estimate of average blood glucose levels over that period. Therefore, HbA1 is commonly used to evaluate long-term glycemic control (3). Hence, HbA1c reflects long-term glycemic control and its relation to the extent of CGM-glucometer differences should be examined.

Body Mass Index (BMI) is calculated by dividing a person's weight in kilograms by the square of their height in meters (kg/m^2) (4). BMI is a simple, widely used screening measure to estimate whether an adult's body weight is healthy relative to their height. While BMI does not directly measure body fat, it is utilized to categorize individuals as underweight, normal weight, overweight, or obese, and to examine potential health risks associated with obesity (4). Similarly, BMI has been suggested to influence glucose measurement accuracy, although evidence remains mixed (5). Therefore, the present study aimed to investigate the relationship between CGM-glucometer differences, HbA1c, and BMI, and to evaluate whether HbA1c and BMI can predict the observed differences.

MATERIALS AND METHODS

Participants. The study included 44 pregnant women. Demographic and clinical characteristics were recorded, including body mass index (BMI), and hemoglobin A1c (HbA1c). All participants underwent both continuous glucose monitoring (CGM) and glucometer measurements.

Measures. The primary variable of interest for our experimental design was the difference between CGM readings and standard glucometer measurements, recorded in mg/dL (CGM-diff). HbA1c was measured as a percentage using standard laboratory assays. For some statistical analyses, HbA1c was categorized based on a threshold of 5.9% into lower risk/normal (<5.9%) and higher risk/elevated (≥5.9%) (6). BMI was calculated as weight in kilograms divided by height in meters squared (kg/m^2) (4).

Procedures. Participants underwent simultaneous CGM and glucometer glucose measurements. Data for CGM-diff, HbA1c, and BMI were collected and entered into the SPSS data set prior to the statistical analysis.

Statistical Analysis. All statistical analyses were conducted using SPSS. An independent samples t-test was performed to compare CGM differences between patients with HbA1c <5.9% and ≥5.9%. Pearson correlations were also calculated to examine the relationships between CGM-glucometer differences and the continuous variables HbA1c and BMI. Finally, a multiple linear regression was conducted to assess whether HbA1c and BMI predicted CGM-glucometer differences. Model assumptions were evaluated, and statistical significance was set at $p = 0.05$.

RESULTS

Independent Samples t-Test. Our statistical analysis showed that patients with HbA1c ≥ 5.9% had a higher mean CGM-glucometer difference (M = 28.71, SD = 0.73, n = 14) compared to patients with HbA1c < 5.9% (M = 23.17, SD = 0.91, n = 30).

The independent-samples t-test indicated that this difference was statistically significant, t(42) = -19.94, p <0.001, with a mean difference of -5.55 (95% CI (-6.11, -4.99)). In addition, Levene's test confirmed that the assumption of equal variances was met, F = 0.77, p = 0.39. The effect size was very large, Cohen's d = 6.45 (fig. 1).

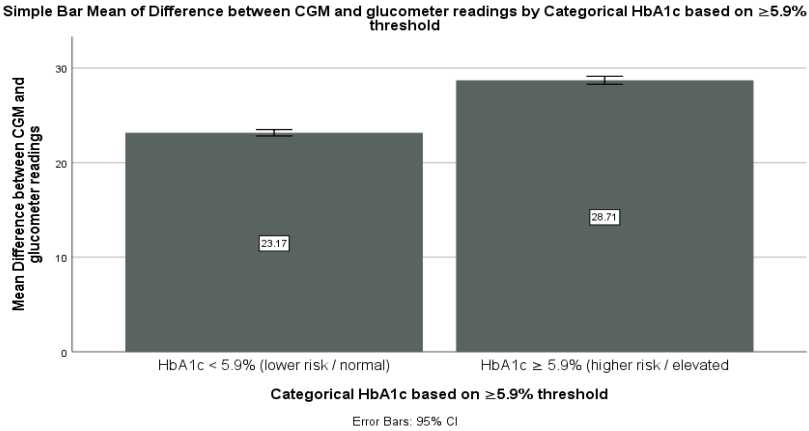

Fig. 1. Mean differences between continuous glucose monitoring (CGM) and glucometer readings for patients with HbA1c <5.9% (lower risk/normal) and ≥5.9% (higher risk/elevated). Error bars represent standard deviations. Patients with higher HbA1c levels exhibited larger CGM-glucometer differences.

Pearson Correlations

Furthermore, a Pearson correlation was conducted to examine the relationship between CGM-glucometer differences and HbA1c. There was a strong, positive correlation, r = 0.996, n = 44, p < 0.001 (fig. 2).

In addition, a second Pearson correlation was used to examine the relationship between CGM-glucometer differences and BMI. The results showed that there was a strong, positive correlation, r = 0.984, n = 44, p < 0.001 (fig. 3).

Multiple Regression

Lastly, a multiple linear regression was conducted to examine whether HbA1c and BMI can predict CGM-glucometer differences. The results showed that the overall model was statistically significant, F(2, 41) = 2910, p < 0.001, and explained 99.3% of the variance in CGM-glucometer differences (Adjusted R^2 = 0.993).

Examination of the coefficients indicated that HbA1c was a significant predictor of CGM-glucometer differences, B = 26.52, SE = 2.18, β = 1.03, t(41) = 12.17, p < 0.001. However, BMI was not a significant predictor, B = -0.05, SE = 0.13, β = -0.03, t(41) = -0.37, p = 0.717. The intercept was B = -134.51, SE = 9.75, t(41) = -13.80, p <0.001 (fig. 4).

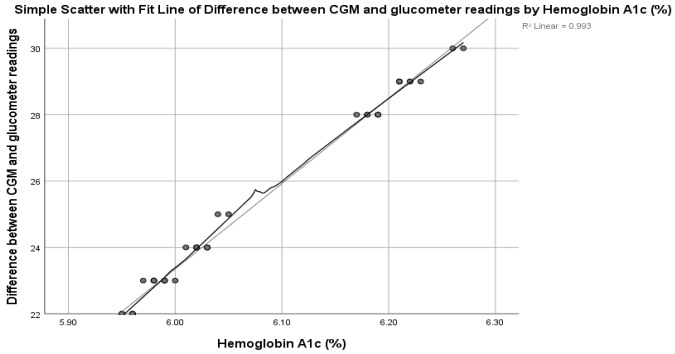

Fig. 2. Scatterplot showing the relationship between CGM-glucometer differences and hemoglobin A1c (HbA1c). The regression line illustrates the strong positive correlation ($r = 0.996$, $p < 0.001$), indicating that higher HbA1c levels are associated with larger CGM-glucometer differences.

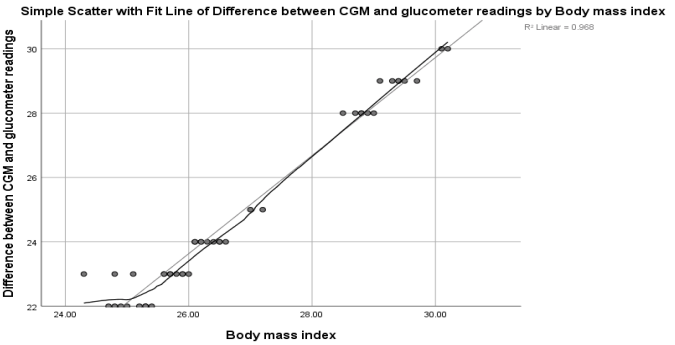

Fig. 3. Scatterplot showing the relationship between continuous CGM-glucometer differences and body mass index (BMI). The regression line illustrates the strong positive correlation ($r = 0.984$, $p < 0.001$), indicating that higher BMI values are associated with larger CGM-glucometer differences.

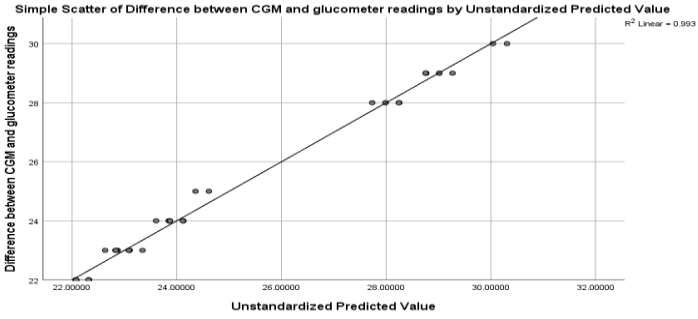

Fig. 4. Scatterplot of observed versus predicted continuous CGM-glucometer differences from the multiple regression model including hemoglobin A1c (HbA1c) and body mass index (BMI) as predictors. The X-axis shows unstandardized predicted values of CGM-glucometer differences, and the Y-axis shows the observed CGM-glucometer differences. Points close to the diagonal line indicate that the model predicts CGM-glucometer differences accurately.

DISCUSSION

The present study examined differences between continuous glucose monitoring (CGM) and glucometer readings in relation to HbA1c and BMI in a sample of 44 pregnant women. The independent-samples t-test indicated that patients with higher HbA1c levels (≥5.9%) exhibited significantly larger differences between CGM and glucometer readings compared to those with lower HbA1c levels. This suggests that HbA1c may be associated with the magnitude of discrepancy between these glucose measurement methods. Our results are in concordance with those found in the literature (7). For example, in a recent study, Lai *et al*. (2023) reported that in gestational diabetes patients with HbA1c < 6%, CGM reduced the mean glucose difference to around 23 mg/dL, closely matching our subgroup with HbA1c < 5.9%, which had a mean difference of 23.17 mg/dL (8).

In addition, our Pearson correlations revealed very strong positive relationships between CGM-glucometer differences and both HbA1c ($r = 0.996$) and BMI ($r = 0.984$). These findings indicate that as HbA1c or BMI increases, the difference between CGM and glucometer readings also increases. In another recent study on this subject, Zhu *et al*. demonstrated that CGM use in gestational diabetes resulted in a mean HbA1c of 6.0% and improved glucose detection, aligning with our results and the resulted high correlation of HbA1c with CGM-glucometer differences (9).

Ultimately, our multiple regression analysis further clarified the predictive role of these variables. While the overall model explained a very high proportion of the variance in CGM differences ($R^2 = 0.993$), only HbA1c emerged as a significant predictor. BMI did not significantly contribute to the model, suggesting that, in this dataset, HbA1c is the primary driver of CGM-glucometer discrepancies. Although previous work has demonstrated robust associations between HbA1c and CGM-derived metrics such as mean glucose (10), few studies have directly assessed whether HbA1c predicts the magnitude of discrepancy between CGM and glucometer readings, underscoring the novelty of our experimental design. Consistent with Guo *et al*, who reported a weak association between higher BMI and larger CGM-glucometer differences (11), our regression analysis also indicated that BMI was not a significant predictor, suggesting a minimal effect of BMI on glucose measurement discrepancies.

Taken together, these results highlight the potential importance of HbA1c in understanding differences between CGM and glucometer readings. Although BMI was strongly correlated with CGM-glucometer differences, it did not remain a significant predictor when considered alongside HbA1c, indicating potential collinearity between the two variables.

CONCLUSIONS

Our findings align with previous studies demonstrating that continuous glucose monitoring can detect fluctuations missed by home glucose monitoring (12) and that higher HbA1c is associated with larger CGM-glucometer differences (13, 14).

These results provide a foundation for further investigation into the factors influencing CGM accuracy, particularly in populations with elevated HbA1c. Future studies should explore additional clinical and behavioral variables that may contribute to these observed measurement discrepancies.

BDNF AND ALOX12 DURING ANTIDEPRESSANT TREATMENT IN MAJOR DEPRESSION: A LONGITUDINAL STUDY (Abstract): This study investigated the longitudinal dynamics of brain-derived neurotrophic factor (BDNF) and arachidonate 12-lipoxygenase (ALOX12) during antidepressant treatment in patients with major depression. **Materials and methods**: Twenty-six patients were assessed at baseline, 4 weeks, and 8 weeks. Depressive and anxiety symptoms were measured using HAM-D and HAM-A, and plasma BDNF and ALOX12 levels were quantified using ELISA. **Results**: HAM-D decreased from 31.0 to 23.0 and HAM-A from 28.0 to 18.0. BDNF increased from 0.87 to 5.33, while ALOX12 decreased from 1.39 to 0.22 ($p<0.001$), with the largest change between weeks 4 and 8; ALOX12 at 8 weeks correlated inversely with HAM-D ($r = -0.416$; adjusted $r = -0.515$). **Conclusions**: BDNF and ALOX12 showed distinct temporal patterns. BDNF increase and ALOX12 reduction occurred without significant associations between their changes. **Keywords**: MAJOR DEPRESSION; BDNF; ALOX12; BIOMARKERS.

INTRODUCTION

Major depression is a clinical condition defined by persistent low mood, anhedonia, cognitive impairment, and somatic symptoms that impair daily functioning (1). The clinical presentation varies across individuals, with differences in symptom profiles, illness trajectory, and comorbidity patterns. This variability also extends to treatment response. A substantial proportion of patients fail to achieve full remission despite adequate pharmacological intervention. Data from the STAR*D study indicate remission rates of approximately 28–33% following first-line treatment, highlighting the limited effectiveness of standard approaches in a large segment of patients (2).

The disorder lacks a single identifiable biological mechanism. Structural and functional alterations have been described in corticolimbic circuits, including the prefrontal cortex, hippocampus, amygdala, and striatum (3). Cellular findings include reduced synaptic density, dendritic retraction, and altered excitatory and inhibitory neurotransmission (4, 5). Inflammatory activation and oxidative stress have been consistently reported, with increased circulating

cytokines and elevated markers of oxidative damage (6-8). These findings indicate a disorder involving multiple interacting biological systems rather than a unitary pathophysiological process.

Numerous biomarkers have been investigated in psychiatric disorders, particularly in depression. These include inflammatory markers, oxidative stress indicators, neurotrophic factors, and metabolic parameters. Nonetheless, no biomarker has demonstrated sufficient sensitivity and specificity for routine clinical use. Findings remain inconsistent across studies, influenced by methodological variability, heterogeneity of patient populations, and differences in biological sampling. Current research has shifted toward examining dynamic biological changes and interactions between systems rather than relying on single-marker approaches (9-12).

Brain-derived neurotrophic factor is one of the most extensively studied molecules in depression. It is involved in neuronal survival, synaptic plasticity, and activity-dependent signaling. BDNF is widely expressed in corticolimbic regions implicated in mood regulation. It's signaling includes functionally distinct isoforms, with mature BDNF promoting synaptic strengthening through TrkB receptors and proBDNF associated with synaptic weakening via p75 receptors (13, 14). Experimental studies have shown reduced BDNF expression following stress exposure and restoration after antidepressant treatment (13-15). Clinical studies report lower peripheral BDNF levels in depression and increases following treatment, although effect sizes are moderate and variability is high (16-18).

Peripheral BDNF reflects both central and systemic sources. Transport across the blood–brain barrier has been demonstrated, although circulating levels are influenced by platelet release and peripheral production (19). Associations with symptom severity are inconsistent. Changes over time appear more informative than baseline levels, particularly in relation to treatment response. These characteristics position BDNF as a marker of neuroplastic processes rather than a diagnostic indicator.

Lipid-mediated pathways represent another component of cellular stress response. Polyunsaturated fatty acids, including arachidonic acid, are integral to neuronal membranes and serve as precursors for bioactive lipid mediators (20). Enzymatic pathways involving cyclooxygenases and lipoxygenases generate molecules that regulate inflammation, oxidative balance, and intracellular signaling (21). Lipoxygenases catalyze the formation of oxidized lipid derivatives that influence membrane integrity and cellular responses to stress (22).

Arachidonate 12-lipoxygenase, encoded by the ALOX12 gene, converts arachidonic acid into 12-hydroxyeicosatetraenoic acid and related metabolites (23). Experimental data show activation of this pathway under conditions of oxidative stress, leading to lipid peroxidation, calcium dysregulation, and neuronal injury (24). Increased expression has been observed in models of cerebral ischemia, with reduced damage following enzyme inhibition (25). This suggests involvement in redox-sensitive cellular processes.

Clinical evidence linking ALOX12 to psychiatric disorders remains limited. Genetic association studies report relationships with bipolar disorder (26). Neuroimaging and genetic analyses suggest associations with cortical structural changes in

stress-related conditions (27). Experimental models demonstrate modulation of lipoxygenase-derived metabolites under chronic stress, particularly in reward-related brain regions (28). Direct clinical data on major depression are scarce, which limits interpretation but highlights the need for longitudinal investigation of this pathway.

Inflammatory, oxidative, and neurotrophic systems interact at multiple levels. Cytokines influence neurotransmitter systems and reduce neurotrophic support, with documented effects on monoaminergic transmission and BDNF expression (29, 30). Oxidative stress affects membrane integrity, mitochondrial function, and intracellular signaling pathways, contributing to neuronal dysfunction (6, 8). These processes converge on mechanisms regulating synaptic plasticity and neuronal adaptation, with inflammation and oxidative stress both implicated in impaired neurogenesis and synaptic remodeling (31, 32). BDNF and lipid-mediated pathways may represent distinct components of these interactions, reflecting different aspects of the biological response to stress and cellular injury (20, 22).

The present study investigates the dynamics of BDNF and ALOX12 during antidepressant treatment in patients with major depression. Biological assessments are performed at baseline, before treatment initiation, and at subsequent time points during treatment. Clinical evaluation is conducted using standardized measures of depressive and anxiety symptom severity, allowing examination of associations between biomarker changes and symptom trajectories.

MATERIALS AND METHODS

This study was designed as a prospective, longitudinal observational investigation conducted between January and June 2025 at the Socola Institute of Psychiatry in Iasi, Romania. The study was approved by the Ethics Committee of Grigore T. Popa University of Medicine and Pharmacy, in Iasi, Romania and the Socola Institute of Psychiatry. All participants provided written informed consent before inclusion.

Participants were evaluated at three predefined time points: baseline (T0), before initiation of pharmacological treatment, 4 weeks after treatment initiation (T1), and 8 weeks after treatment initiation (T2). All assessments were performed under standardized conditions.

A total of 26 patients aged between 24 and 63 years were included in this study. Participants were recruited from inpatient admissions and subsequently monitored in an outpatient setting, with rehospitalization when clinically indicated. Inclusion criteria comprised age between 18 and 65 years, a diagnosis of severe depressive episode or recurrent depressive disorder, and absence of psychiatric medication in the two weeks preceding baseline evaluation. Exclusion criteria included bipolar disorder, psychotic disorders, significant cognitive impairment, chronic alcohol or substance use, pregnancy or breastfeeding, severe untreated medical comorbidities, positive serology for hepatitis B, hepatitis C or HIV, known hypersensitivity to prescribed medications, poor compliance, and the presence of active suicidal ideation or aggressive behavior at baseline.

Clinical evaluation was performed by the same clinician at all time points and included both a general medical examination and a structured psychiatric assessment. Depressive symptom severity was measured using the 17-item Hamilton De-

pression Rating Scale, while anxiety symptoms were assessed using the Hamilton Anxiety Rating Scale. Anthropometric measurements were obtained for the calculation of body mass index (BMI), and relevant demographic and clinical variables, including smoking status and alcohol consumption, were recorded due to their potential influence on inflammatory and metabolic processes.

Venous blood samples were collected at each time point between 08: 00 and 09: 00 following an overnight fast of at least 8 hours in order to minimize circadian and metabolic variability. Samples were drawn into EDTA tubes and processed within 30 minutes. Platelet-poor plasma was obtained using a two-step centrifugation protocol, aliquoted into polypropylene tubes, and stored at −80 °C until analysis. Samples from the same participant were analyzed within the same experimental run to reduce inter-assay variability, and repeated freeze–thaw cycles were avoided.

Plasma concentrations of brain-derived neurotrophic factor were determined using a commercially available sandwich ELISA kit (IBL International GmbH/Tecan, catalogue number RB59041), following the manufacturer's instructions. All samples and standards were analysed in duplicate. The same applies to plasma levels of arachidonate 12-lipoxygenase, which were measured in duplicate using a commercially available ELISA kit specific for human ALOX12 (FineTest, catalogue number EH1980) according to the manufacturer's protocol.

Pharmacological treatment was initiated after baseline assessment and was prescribed individually by the treating psychiatrist in accordance with current clinical guidelines. The study followed a naturalistic design, with no intervention from the investigators in treatment selection or dosing.

Statistical analyses were performed using IBM SPSS Statistics v28.0. Data distribution was assessed using the Shapiro–Wilk test. As the data were not normally distributed, non-parametric tests were applied. Changes across the three time points were analyzed using the Friedman test, with pairwise comparisons performed using the Wilcoxon signed-rank test. Associations between biomarker levels and clinical measures were evaluated using Spearman's rank correlation coefficient. Statistical significance was set at $p < 0.05$ (two-tailed).

RESULTS

Clinical and biomarker evolution

At baseline, patients presented with high levels of depressive and anxiety symptoms, with median HAM-D and HAM-A scores of 31.0 and 28.0, respectively, indicating moderate-to-severe symptomatology. After 8 weeks of treatment, both measures showed a clear reduction, with median values decreasing to 23.0 for HAM-D and 18.0 for HAM-A (tab. I).

In parallel, biological markers showed distinct temporal patterns. Serum BDNF levels increased markedly over the course of treatment, from a median of 0.87 at baseline to 5.33 at 8 weeks. In contrast, ALOX levels showed a progressive decrease, from a median of 1.39 at baseline to 0.22 at 8 weeks (tab. I).

These temporal changes are illustrated in figure 1, which shows a progressive reduction in ALOX values over time, with the most pronounced decrease observed at 8 weeks. The distribution also indicates greater variability at baseline, followed by a reduction in dispersion at subsequent time points.

TABLE I.

Descriptive statistics of clinical variables and biomarkers across time points

Variable	T0 Median (IQR)	T1 Median (IQR)	T2 Median (IQR)
ALOX	1.39 (1.04–3.41)	1.17 (0.94–1.41)	0.22 (0.21–0.23)
HAM-D	31.0 (29.75–32.0)	30.0 (28.0–31.25)	23.0 (17.5–24.25)
HAM-A	28.0 (26.0–30.0)	24.0 (22.0–26.0)	18.0 (18.0–20.0)
BDNF	0.87 (0.54–1.43)	5.11 (2.53–8.89)	5.33 (3.15–9.42)

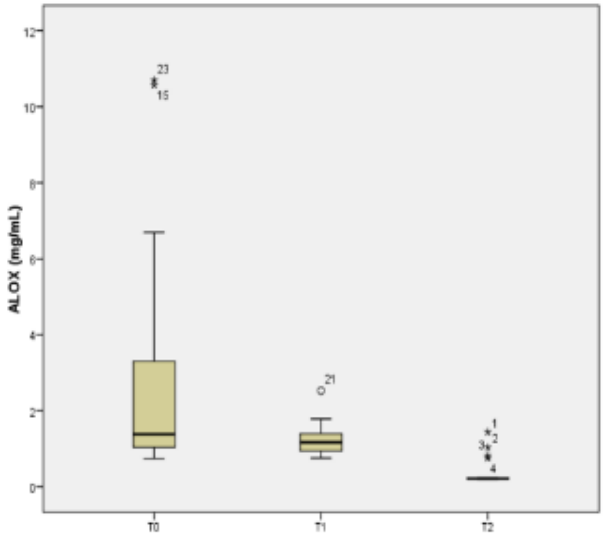

Fig. 1. Evolution of ALOX levels at T0, T1, and T2 during treatment

Given the non-normal distribution of most variables, non-parametric analyses were applied. The Friedman test revealed a significant overall effect of time on ALOX levels ($\chi^2(2) = 34.462$, $p < 0.001$). Mean ranks decreased progressively from T0 (2.62) to T1 (2.31) and T2 (1.08), indicating a consistent downward trajectory.

Post-hoc pairwise comparisons showed that the reduction between baseline and 4 weeks did not reach statistical significance after Bonferroni correction ($p = 0.027$). In contrast, differences between baseline and 8 weeks, as well as between 4 and 8 weeks, were statistically significant (both $p < 0.001$), indicating that the main change in ALOX occurred during the later phase of treatment. Stratified analyses across antidepressant classes showed similar temporal patterns of ALOX reduction across all groups (tab. II). Baseline values were numerically higher in the tricyclic antidepressant group, although interpretation is limited due to the small subgroup sizes. No statistically significant differences between classes were observed (Kruskal–Wallis χ^2 (3) = 6.769, $p = 0.080$), although the highest mean rank change was noted in the multimodal serotonergic group.

TABLE II.

Descriptive statistics stratified by antidepressant class

Variable	Time	SMS (n=4)	SNRI (n=9)	SSRI (n=10)	TCA (n=3)
HAM-D	T0	30.5 (30.0–31.5)	32.0 (31.0–32.0)	32.0 (30.0–32.0)	29.0 (28.5–29.0)
	T1	30.0 (29.0–30.0)	30.0 (30.0–32.0)	30.5 (28.0–32.0)	–
	T2	21.0 (16.5–24.0)	24.0 (20.0–25.0)	21.0 (16.0–24.0)	24.0 (20.0–25.0)
HAM-A	T0	28.0 (27.0–29.0)	28.0 (28.0–30.0)	26.0 (26.0–30.0)	24.0 (24.0–26.0)
	T1	25.0 (22.0–27.0)	26.0 (22.0–26.0)	23.5 (20.0–26.0)	22.0 (22.0–24.0)
	T2	19.0 (17.0–21.0)	20.0 (18.0–20.0)	18.0 (16.0–20.0)	20.0 (19.0–20.0)
BDNF	T0	0.50 (0.40–0.86)	0.86 (0.63–1.33)	0.98 (0.73–1.55)	0.72 (0.59–1.25)
	T1	9.09 (2.52–18.70)	5.39 (4.17–5.88)	3.67 (2.33–11.25)	5.46 (3.90–6.04)
	T2	9.81 (2.84–20.70)	5.65 (4.29–6.25)	4.15 (3.23–11.44)	5.41 (4.12–6.05)
ALOX	T0	1.10 (0.87–1.32)	1.21 (0.91–2.59)	1.60 (1.06–3.71)	3.31 (2.19–5.00)
	T1	1.37 (1.28–1.58)	1.07 (0.91–1.56)	1.15 (0.94–1.37)	1.15 (1.07–1.33)
	T2	0.52 (0.22–0.93)	0.22 (0.21–0.22)	0.22 (0.22–0.24)	0.23 (0.22–0.23)

*The symbol "–" indicates that the interquartile range (IQR) could not be calculated due to the small subgroup size (particularly TCA, n=3) and insufficient variability in the data at that time point.

Associations between biomarkers and clinical outcomes

Correlation analyses at 8 weeks revealed a significant negative association between ALOX levels and depressive symptom severity. Higher ALOX levels were associated with lower HAM-D scores in both zero-order analysis ($r = -0.416$, $p = 0.035$) and after adjustment for age and body mass index (partial $r = -0.515$, $p = 0.010$) (tab. III).

This relationship is illustrated in figure 2, which shows an inverse relationship between ALOX and HAM-D scores.

TABLE III.

Spearman and partial correlations at 8 weeks

Variable pair	r (zero-order)	p (zero-order)	r (partial)	p (partial)	Significant
HAM-D T2 vs ALOX T2	−0.416	0.035	−0.515	0.010	Yes
HAM-D T2 vs BDNF T2	−0.400	0.043	−0.402	0.052	Trend
HAM-D T2 vs Age	+0.501	0.009	—	—	Yes
HAM-D T2 vs BMI	+0.391	0.048	—	—	Yes
HAM-A T2 vs ALOX T2	−0.211	0.301	−0.240	0.259	No
HAM-A T2 vs BDNF T2	−0.250	0.218	−0.338	0.106	No
BDNF T2 vs ALOX T2	+0.282	0.163	+0.285	0.178	No
Age *vs.* BMI	+0.701	<0.001	—	—	Yes

In contrast, no significant associations were observed between ALOX levels and anxiety symptoms (HAM-A) at 8 weeks, either before or after adjustment (tab. III), suggesting the specificity of this relationship for depressive symptomatology.

BDNF levels at 8 weeks showed a negative association with HAM-D scores in zero-order analysis ($r = -0.400$, $p = 0.043$), which remained at a trend level after adjustment (partial $r = -0.402$, $p = 0.052$). The magnitude of this association remained stable after controlling for demographic variables.

No significant correlations were identified between changes in ALOX and changes in clinical scores or BDNF levels (all $p > 0.05$). A strong negative correlation was observed between baseline ALOX and its change over time ($r_s = -0.833$, $p < 0.001$), although this finding is influenced by mathematical coupling and should be interpreted cautiously.

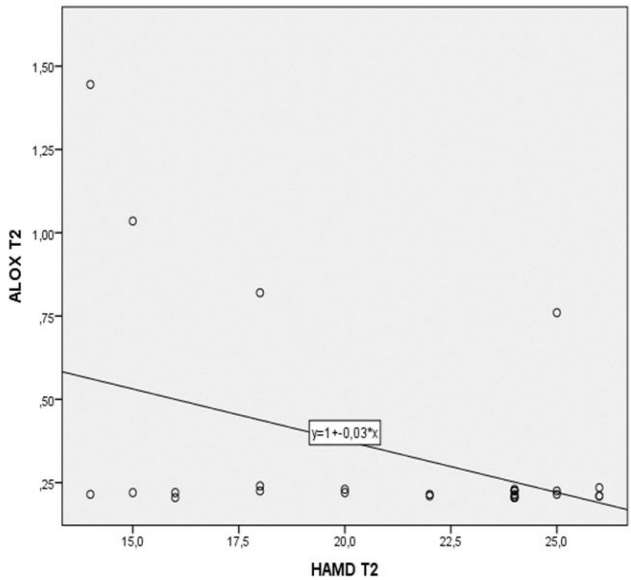

Fig. 2. Association between depressive symptom severity at 8 weeks and ALOX levels at T2

Age and body mass index were both positively associated with HAM-D scores at 8 weeks ($r = +0.501$, $p = 0.009$ and $r = +0.391$, $p = 0.048$, respectively). These variables were strongly correlated with each other ($r = +0.701$, $p < 0.001$), supporting their inclusion as covariates in adjusted analyses.

Exploratory subgroup and predictive analyses

No statistically significant differences in ALOX change were observed between responders and non-responders after 8 weeks of treatment (Mann–Whitney $U = 35.5$, $p = 0.269$), although responders showed higher mean ranks, suggesting a tendency toward greater reduction.

The distribution of ALOX values across these groups is shown in fig. 3 and fig. 4. Responders exhibited more homogeneous changes, whereas non-responders showed greater variability.

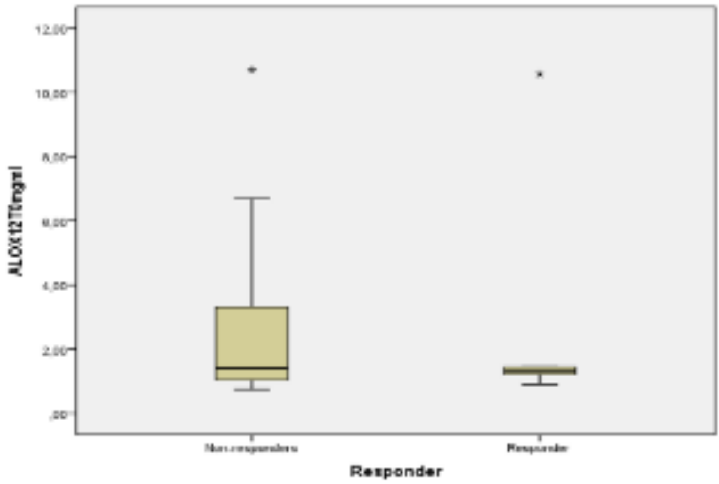

Fig. 3. Comparative boxplot of baseline serum ALOX levels in responders and non-responders

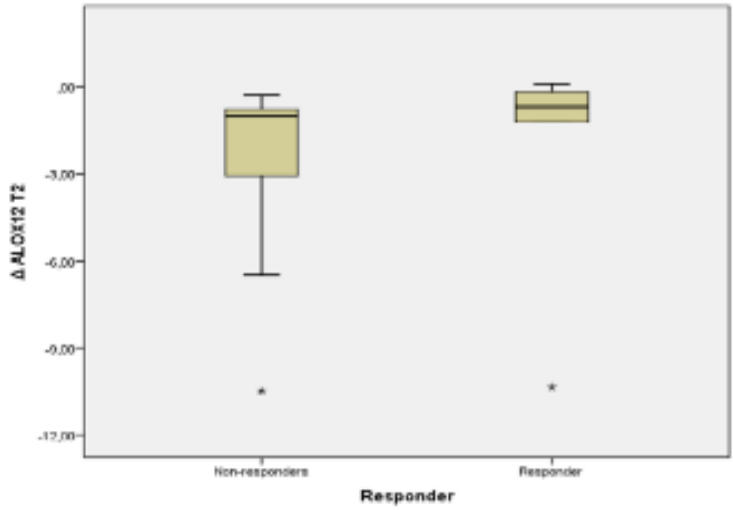

Fig. 4. Change in ALOX levels between T0 and T2 in responders and non-responders

Receiver operating characteristic analysis did not demonstrate predictive value of baseline ALOX levels for treatment response (AUC = 0.510, p = 0.948; 95% CI: 0.232–0.787).

Exploratory analyses of demographic and lifestyle factors did not identify significant associations with ALOX change (all p > 0.05) (tab. IV). The closest trend toward statistical significance was observed for smoking status (p = 0.143), with smokers showing higher mean ranks compared to non-smokers, which may indicate a more pronounced change in ALOX in this subgroup. In the absence of statistical significance, this observation remains exploratory.

TABLE IV.
Exploratory subgroup analyses of ALOX change

Variable	Group	N	Mean Rank	Mann-Whitney U	Z	p-value
Sex	Female	20	13.03	50.500	-0.578	0.563
	Male	6	15.08			
Residence	Rural	15	14.30	70.500	-0.623	0.533
	Urban	11	12.41

Occupation status	Employed	12	13.33	82.000	-0.103	0.918
	Unemployed	14	13.64			

DISCUSSION

This study identified three principal observations: a reduction in depressive and anxiety symptom severity over 8 weeks, a marked increase in BDNF levels, and a progressive decrease in ALOX levels. The reduction in depressive severity was accompanied by an increase in BDNF and a decrease in ALOX, although these biological changes followed distinct temporal patterns and showed limited direct correlation with each other.

The absence of significant correlations between changes in ALOX and changes in clinical scores suggests that these markers capture partially independent biological processes. This dissociation is consistent with previous evidence indicating that biological markers in depression often reflect heterogeneous mechanisms rather than a unified pathophysiological pathway (33).

Depressive and anxiety symptoms showed a progressive reduction over the 8-week treatment period, with the most substantial improvement observed at the final time point. This temporal pattern aligns with clinical data indicating that antidepressant effects accumulate over several weeks rather than emerging immediately (34, 35). The magnitude of symptom reduction observed in this study is consistent with large clinical datasets showing partial response rather than full remission in most patients during early treatment phases (35). Previous studies have shown that early symptom reduction does not necessarily correspond to full biological normalization, supporting the interpretation of clinical improvement as a gradual and multidimensional process (36).

BDNF levels increased significantly over the course of treatment, consistent with the neurotrophic hypothesis of depression. This increase is in line with meta-

analytic findings reporting elevated peripheral BDNF following antidepressant treatment (16, 18). However, the lack of strong correlations between BDNF changes and symptom improvement in this study reflects the variability described in the literature. Several longitudinal analyses have reported weak or absent associations between peripheral BDNF changes and clinical outcomes, suggesting that BDNF does not function as a direct proxy for symptom severity (16, 17, 33).

The negative association between BDNF and depressive severity at endpoint, although modest, is consistent with evidence that reduced neurotrophic support is linked to impaired synaptic plasticity (4, 13). Some studies indicate that inflammatory processes can suppress BDNF expression, while BDNF itself may regulate neuroinflammatory activity, supporting a bidirectional relationship between these systems (30, 31).

ALOX levels showed a progressive and statistically significant decrease over time, with the most pronounced reduction occurring between weeks 4 and 8. This delayed dynamic suggests that ALOX-related pathways may reflect biological processes evolving later in treatment. The absence of significant correlations between ALOX changes and symptom improvement suggests that this marker does not directly reflect clinical response. However, the significant inverse association between ALOX levels and depressive severity at the endpoint indicates a more complex relationship. Higher ALOX levels at 8 weeks were associated with lower depressive severity, a finding that does not align with a simple pro-inflammatory or neurotoxic interpretation. This pattern may reflect compensatory or regulatory mechanisms within lipid signaling pathways. Lipid mediators derived from arachidonic acid metabolism participate in both pro-inflammatory and resolution processes, and their functional role may depend on context, timing, and cellular environment (20, 37).

The findings indicate that BDNF and ALOX reflect different aspects of biological response during antidepressant treatment. BDNF appears to capture processes related to neuroplastic adaptation, while ALOX may reflect changes in lipid-mediated oxidative pathways that evolve later in treatment. The absence of predictive value of baseline ALOX for treatment response suggests that this marker is more relevant for monitoring biological changes over time rather than predicting outcomes. The variability observed in non-responders further supports the presence of biological heterogeneity within depressive disorders (38, 39).

The relatively small sample size limits statistical power and may reduce the ability to detect subtle associations. The use of peripheral biomarkers introduces uncertainty regarding their relationship to central nervous system processes, particularly for BDNF, where peripheral levels may not directly reflect brain concentrations (17). The naturalistic design introduces variability related to treatment heterogeneity, although it enhances ecological validity. The absence of a control group limits causal interpretation of observed changes.

CONCLUSIONS

The study demonstrates that antidepressant treatment is associated with increased BDNF and decreased ALOX levels over time, alongside clinical improvement. These markers show distinct temporal patterns and limited direct association with each other.

BDNF appears to reflect neuroplastic processes associated with treatment, while ALOX may represent a separate biological

pathway related to oxidative and lipid-mediated mechanisms. Their combined assessment provides a broader perspective on biological changes occurring on treatment.

Longitudinal evaluation of multiple biomarkers may offer a more accurate representation of the biological processes underlying treatment response in major depression.

INCREASING INCIDENCE OF RECURRENT *CLOSTRIDIUM DIFFICILE* INFECTION (Abstract): *Clostridium difficile* infection continues to be a major cause of infectious enterocolitis, commonly associated with antibiotic use. Infection can lead to relapses, reason why it is considered by clinicians a true challenge. **Aim**: To determine the incidence of recurrent *Clostridium difficile* infection in patients admitted to the Iasi Infectious Diseases Hospital over a six-month period. **Material and methods**: Of the 195 admitted patients, 46 presented for the recurrence of colitis. Data from medical records had been used to identify the patients who met the inclusion criteria. **Results**: Most of the 46 relapses were recorded in individuals aged over 60 with multiple associated comorbidities. The test for *Clostridium difficile* toxin was positive in a significant percentage of cases and the treatment consisted in the administration of vancomycin and normix alone or in combination, along with the treatment of comorbidities. **Conclusions**: Once a relapse occurs the risk of a second relapse is rising, the elderly being most vulnerable. The use of antibiotics should be limited to situations where they are absolutely needed.
Keywords: RECURRENT CLOSTRIDIUM DIFFICILE INFECTION, VANCOMYCIN, COMORBIDITIES, MULTIDISCIPLINARY COLLABORATION.

Ubiquitous bacterium, *Clostridium difficile* (*C. difficile*) has been incriminated in the causation of infectious enterocolitis, the most common cause of nosocomial diarrhea. The bacterium is part of the normal intestinal microbiota in 3% of the adult population, 10-30% of hospitalized patients, and 60-70% of infants.

C. difficile enterocolitis can occur at any age after antibiotic administration and rarely spontaneously. Patients who receive antibiotic therapy are at 7-10 times higher risk for developing the disease (1).

Also, patients who are hospitalized for other diseases and those with gastrointestinal surgery in recent history are at higher risk, the incidence being higher among people over the age of 65 (2).

The disease can be cured, may recur or can be fatal. Recurrent *C. difficile* infections represent a major clinical challenge due to their growing incidence. According to the Center for Disease Prevention and Control each year *C. difficile* is involved in

over 500,000 illnesses and one in five people diagnosed with *C. difficile* colitis returns due to the recurrence of symptoms and positivity of stool cultures. Once a relapse occurs, the risk of a secondary recurrence is 45%. It is also estimated that this bacillus is the cause of more than 15,000 deaths in people over 65, about one in 11 patients diagnosed with the infection dying within 30 days of diagnosis (3).

The source of infection are people (with C. difficile infection or carriers) who spread the bacteria or contaminate surfaces through hand contact and the environment of patients with colitis induced by this bacterium. Human transmission can be prevented by isolating the *C. difficile* infection cases, the use of gloves and thorough handwashing, environmental disinfection, and by educating the patients/ families (1, 4).

Recurrences are caused by reinfection with the original C. difficile strain (due to the presence of resistant spores) and/or reinfection with a new strain from the environment, the exact cause being difficult to determine. What can be said for sure it is that resistant strains do not exist, and therefore, the treatment may be the same as for the primary infection (5, 7). Treatment options for patients with more than one recurrence are becoming more and more limited. Prolonged use of metronidazole is associated with a risk of neurotoxicity, which is why oral v vancomycin is preferred in these cases. Other drugs have been approved as an alternative treatment for relapses: fidaxomicin, rifaximin, probiotics, ion exchange resins (cholestyramine) or fecal microbiota transplantation (6, 7).

MATERIAL AND METHODS

This retrospective observational study was conducted at the "Sf. Parascheva" Infectious Diseases Hospital from Iasi. It included all patients diagnosed with *C. difficile* colitis admitted between July 1st and December 31st, 2016, the aim being to determine the incidence of recurrent infections. The presence of the causative agent was confirmed by the rapid test for the detection of *C. difficile* toxins A and B, this being the most important inclusion criterion.

A descriptive analysis based on the demographic, clinical, and laboratory data, disease course, therapeutic approach and underlying diseases was carried out using data from patient medical records.

RESULTS

Between July 1st and December 31st, 2016, 195 patients diagnosed with *Clostridium difficile* colitis were admitted. The data collected from medical records as well as from the accompanying documents revealed that 46 patients presented for relapse, the remaining patients being at their first admission for this disease.

The most affected age group was over 60 (71.73% of the cases), with relatively small gender differences (46% women, 54% men). Similar percentages were recorded for the place of residence (54% urban patients, 46% rural patients).

According to history and accompanying documents these 37 patients received antibiotic treatment prior to the first episode of C. *difficile* colitis, the most commonly being used the cephalosporins and fluoroquinolones.

Of the total of 46 patients, 63% were at their first relapse, 17% at the second, and 9% at their third relapse. In 58.69% of the cases, the patients presented themselves directly to our hospital (at the triage or the doctor who had previously treated him),

32.61% of cases were referred by other specialists and only 8.7% of the cases were referrals from family doctors.

The disease had a favorable course in most cases, with remission of diarrheal symptoms and negativizing of *C. difficile* toxin in stools. Three cases had an unfavorable course, resulting in death due to complications of the associated comorbidities. Because in most cases patients were retired (86.95%), they also had several underlying disorders, the most common being the digestive (including liver cirrhosis, hepatitis B, C, colorectal cancer, chronic cholecystitis, gastric/duodenal ulcers), cardiovascular and surgical ones, as shown in figure 1.

Analyzing the observation charts, it was found that all patients had the specific symptoms of the disease (moderate or severe diarrhea, accompanied by abdominal pain), to which symptoms of nausea and loss of appetite were added in 8 (17.4%) patients, vomiting and fever in 5 (10.9%) and 2(4.37%) patients experienced vertigo and abdominal bloating.

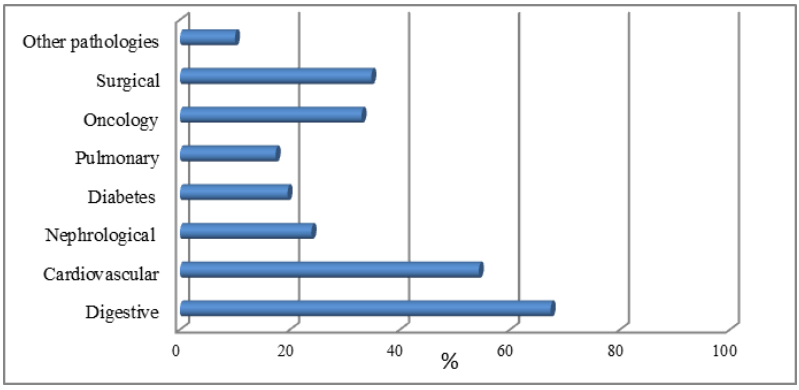

Fig. 1. Distribution of associated comorbidities

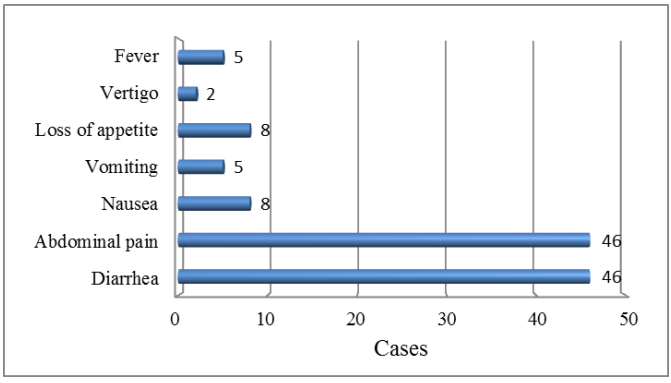

Fig. 2. Distribution of cases by associated symptoms

The positive diagnosis is based on the rapid detection of C. difficile toxins A and B in stool samples. In our study group both toxins (A and B) were detected in 80.43% of cases, toxin A alone in 10.9% cases, GDH antigen in 19.5% and 2.17% of the

results identified nontoxigenic strains.

A significant number of patients also presented clinical-biological changes associated with the disease: anemia (54.34% of cases), predominantly microcytic anemia, the most frequent cause being iron deficiency, or secondary, intrainfectious hypokalemia (39.13% of cases) and hypoproteinemia (39.95% of cases).

Most patients had been hospitalized for more than 8 days (range 3-26 days). All patients received antibiotic treatment during hospital stay. Therapy was initiated after the confirmation of relapse, and its average duration was 7-10 days. Vancomycin treatment was instituted in 80.43% of relapses, normix in 34.78%, and 15.21% of cases were treated with vancomycin and normix combination. In addition to the treatment for *C. difficile* colitis, 67.4% of the patients also received treatment for the underlying diseases.

In the case of patients with a poor general health status with or with associated comorbidities, intensive care physicians as well as physicians of various specialties were consulted to provide the best recovery therapy.

DISCUSSION

Unfounded use of antibiotics has led to a significant increase in the resistance of microorganisms to antibiotics. A major side effect of unfounded antibiotic use is the increased incidence of post-antibiotic diarrhea.

Any antimicrobial medication with intestinal penetration is thought to trigger the disease, even at very low doses. Therefore, those who received prior antibiotic treatment and the elderly are the most vulnerable groups of patients who can develop *C. difficile* colitis, an infectious disease with interhuman transmission, with increased risk of rebound and death.

The analysis of the data from our study showed that the people aged over 60 years and retired were most commonly affected, with a slightly higher proportion of male and urban population.

Clostridium difficile toxins A and B were positive in most cases, which is essential in the present study, with the occurrence of the specific symptoms of disease in 100% of cases. Patients had multiple associated comorbidities, especially surgical and digestive, but also disturbances in biological assays, which impeded the favorable outcome in three patients who died.

Due to the risk of neurotoxicity of prolonged use of metronidazole, antibiotic therapy with vancomycin (80.43%) and normix (34.78%) alone or in combination was chosen in parallel with the treatment of comorbidities.

CONCLUSIONS

The results of the present study show that recurrences of C. difficile infection are frequently diagnosed in patients with multiple comorbidities, especially surgical and gastrointestinal, and additional risk factors include advanced age and history of cancer that represent major problems in the clinical management of patients with *Clostridium difficile* infection.

Our recommendation for preventing the disease is the limitation of antibiotic use, as well as maintaining proper hygiene (of the skin, surfaces and the environment). Also, observance of the indications on food consumption leads to a favorable course of the disease and prevents relapses.

It can be noted that in case of complex treatments the multidisciplinary approach plays an important role in the evolution of the disease and recovery of patients.

NEWS

HISTOPATHOLOGIC FEATURES OF PROGNOSTIC SIGNIFICANCE IN HIGH-GRADE OSTEOSARCOMA

Osteosarcoma is a malignant mesenchymal neoplasm characterized by bone production. Several types of primary high-grade osteosarcoma are recognized by the World Health Organization, including the "conventional" types encompassed by the chondroblastic, fibroblastic, and osteoblastic subtypes, among others. Despite heterogeneity in histomorphology, most high-grade osteosarcomas receive similar treatment, namely, neoadjuvant chemotheratypically consisting of doxorubicin, cisplatin, and high-dose methotrexate, followed by surgical resection and maintenance chemotherapy. Although many groups have assessed the contribution of clinical parameters—namely, patient age, sex, anatomic site of primary tumor, tumor size, and metastasis at presentation—in predicting survival outcomes for patients with osteosarcoma, there are limited data concerning histopathologic attributes. Histopathologic prognostic factors represent an essential component to the treatment stratification of many types of cancer. The authors suggest that detailed microscopic examination (tumor pleomorphism, mitotic activity, and morphologic subtype) yields useful prognostic information in high-grade osteosarcoma. In biopsy samples, necrosis and chondroblastic differentiation are adverse features. In resections, quantitation of the extent of residual viable tumor may be of greater clinical relevance than attempting to distinguish necrosis from other noncellular elements. In summary, the integration of clinical and microscopic features is a feasible and effective means for improving prognostication in patients with osteosarcoma. The effective stratification of patients using the proposed scoring system merits further investigation, ideally in prospective cohorts, to validate interobserver reproducibility and predictive ability (Chui MH, Kandel RA, Wong M, *et al*. Histopathologic Features of Prognostic Significance in High-Grade Osteosarcoma. *Arch Pathol Lab Med* 2016; 140(11): 1231-1242).

BALANCING THE THROMBOTIC RISK AND THE HEMORRHAGIC RISK IN PATIENTS WITH INFLAMMATORY BOWEL DISEASE AND DEEP VEIN THROMBOSIS - CASE REPORT (Abstract): The thrombotic events occurring in patients with inflammatory bowel disease are currently recognized as a form of extraintestinal manifestation of the disease. We present the case of a 35-year-old Caucasian male with inflammatory bowel disease and deep vein thrombosis, drawing attention to the particularities of the venous thrombotic events in this category of patients: high thrombotic risk, peak incidence at young age, high risk of recurrence. We state the correct anticoagulant treatment based on current evidence and guidelines recommendations, highlighting the importance of a careful assessment of both the thrombotic and hemorrhagic risk of the patient. Special attention has been paid to the new oral anticoagulants and to the latest recommendations of specialized guidelines.
Keywords: ANTICOAGULANTS, VENOUS THROMBOEMBOLISM, INFLAMMATORY BOWEL DISEASE.

Inflammatory bowel disease (IBD) is a chronic inflammatory condition characterized by local and systemic inflammation, predominantly affecting the gastrointestinal tract. The two major forms are Crohn's disease (CD) and ulcerative colitis (UC).

The association between IBD and venous thrombosis was first described in 1936 by Bargen and Barker (1). Further studies (2,3) have shown that IBD patients have a 2 to 3 fold increased risk of developing deep vein thrombosis (DVT) and pulmonary embolism (PE) compared to the general population and the thrombotic risk is almost three times higher in males than in females. No significant differences in the risk of venous thromboembolism (VTE) are found between UC and CD patients (4). The main sites of thrombosis are the deep veins of the lower limbs and the pulmonary system (5). Less frequently, the thrombosis may develop in the cerebrovascular system, hepatic, portal, retinal and mesenteric veins (4).

CASE REPORT

We present the case of a 35-year-old Caucasian male who presented with pain in

his right thigh with a 24-hour onset. The thigh was enlarged in volume, but without changes in color or local temperature. The patient denied any trauma in that area. At the age of 30 he was diagnosed with a limited form of ulcerative colitis (proctosigmoiditis) and at the time of the current presentation he was on treatment with mesalazine 1000 mg twice daily. He was a non-smoker. Venous ultrasound confirmed the deep vein thrombosis of the superficial femoral vein, the fresh thrombus occupying the lower third of the vein. Anemia was absent. The IBD was in remission. The patient's chronic treatment does not favor thrombosis; on the contrary, mesalazine has the advantage of reducing platelet activation.

The anticoagulant treatment was started with low molecular weight heparin (LMWH - enoxaparinum), with favorable outcome. Pain and swelling have rapidly diminished, being absent at discharge. Given the presence of UC, the main challenge was the management of the antithrombotic therapy, because patients with IBD are at high risk of both VTE and gastrointestinal bleeding.

DISCUSSION

We started by evaluating the substrate of the prothrombotic state to fit the current thrombotic event into one of the two categories: provoked or unprovoked DVT.

The genetic mutations which are causes of inherited thrombophilia have similar incidence in IBD patients and in the general population, suggesting that the acquired factors play a crucial role in the occurrence of thrombosis. The clinical studies have shown no association between IBD and Factor V Leiden, prothrombin G20210, MTHFR or Factor XIII val34leu, respectively. Therefore, the available guidelines do not recommend thrombophilia testing in patients with IBD and VTE, including the patients with unprovoked VTE while their IBD is in clinical remission (6). Accordingly, we did not do thrombophilia testing in our patient.

The role of inflammation in IBD pathogeny has been heavily debated over the years. Indeed, the inflammatory cytokines affect the coagulation cascade, fibrinolysis, and platelet functions. Because some of the coagulation factors are also acute-phase reactants, if the prothrombotic state is triggered by the inflammation or represent a feature of the intestinal disease per se is still a matter of debate. More recently, high levels of circulating microparticles have been found in IBD patients during active phases of the disease. Decreased natural anticoagulants (antithrombin III activity, proteins C and S, tissue factor pathway inhibitor) (7) and a disturbed fibrinolysis (reduction in fibrinolysis activators such as tPA and increase in inhibitors such as PAI-1 and TAFI) complete the complex anomalies of the coagulation system. Endothelial dysfunction and the quantitative, morphological and qualitative alterations in platelet characteristics also contribute to the prothrombotic state of this disease.

Despite the many above mentioned, inflammation does not seem to be the main player in this disease. Miehsler et al. (8) compared the thromboembolic risk of patients with IBD with that of patients with celiac disease and rheumatoid arthritis. While an association between the high frequency of thromboembolic events and IBD was established, no such association was found in patients with other systemic inflammatory conditions such as celiac disease and rheumatoid arthritis. A pro-

coagulant tendency unequivocally exists in IBD patients, but unfortunately no abnormality has been shown to be a marker for the thrombotic risk in IBD.

The incidence of VTE in the general population increases with age, but in IBD patients the highest risk for VTE is observed among those less than 40 years of age, with an incidence rate ratio for VTE of 4.5 when compared with the non-IBD patients (9, 10). Our patient was 35 years old at the time of the thrombotic event, so he fit the pattern. The younger the age at the first thrombotic episode is, the higher the risk of recurrence (3). The thromboembolic complications occur more frequently during the active phases of the disease and in patients with extended disease (11). Moderate and severe disease flares significantly increase the risk of VTE in IBD patients and should be considered as a provoking factor. But the thromboembolic complications are also seen in almost one third of the patients with partial or full remission (11). In our case, the patient had a limited form of disease and he was in remission when the thrombotic event occurred, so disease flares were excluded as provoking factor. No other provoking factors have been identified. IBD patients who experience their first episode of unprovoked VTE have a 33% risk of recurrence within 5 years. The risk of recurrence is 2.5-fold higher than that of non-IBD patients after an initial episode of unprovoked VTE (3).

All these data suggest that IBD is a continuing risk factor for recurrent VTE and, therefore, indefinite anticoagulant therapy should be recommended in patients who are diagnosed with their first episode of unprovoked proximal DVT when in clinical remission (12). Is seems that benefits of long-term anticoagulation in reducing recurrent VTE in IBD patients who have had unprovoked VTE outweigh the risks of the associated bleeding (2). The need for anticoagulation should be revised at least annually.

The first European evidence-based consensus on extraintestinal manifestations in inflammatory bowel disease (13) states that the treatment of VTE in IBD patients follows the same protocols as for non-IBD patients. So, we start the treatment with LMWH. Long-term anticoagulant treatment usually comprises a vitamin K antagonist (VKA) or a non-vitamin K antagonist oral anticoagulant (NOAC). Meta-analysis regarding efficacy and safety of NOACs as compared with VKA in the treatment of VTE have shown that NOACs have comparable efficacy to that of VKAs and are associated with a significantly lower risk of bleeding complications (odds ratio 0.63, 95% CI 0.44-0.90) (14). In terms of major gastrointestinal bleeding, a recent meta-analysis (15) reported low relative risk for rivaroxaban and apixaban and elevated relative risk for dabigatran when compared to warfarin. This might be explained by an individual drug effect or a difference between drug classes (FIIa inhibitors and FXa inhibitors). No separate data regarding bleeding risk were reported for edoxaban.

A meta-analysis of the clinical trials in the atrial fibrillation population confirmed a significantly increased risk of gastrointestinal hemorrhage with NOACs compared with VKA (16). Apixaban was not associated with this bleeding outcome in either the VTE or atrial fibrillation studies (17), so this medication may be more appropriate in patients who experienced a gastrointestinal hemorrhage or who are at risk for this complication. No significant difference was found between NOACs and comparators

for extended treatment of VTE.

All studies on NOACs for VTE treatment suggest that they have comparable efficacy to that of VKAs with a more favorable safety profile, but there is no direct evidence for their use in IBD patients yet, so our treatment respected the so far existing evidence. We were able to find just one case report (18) of NOAC use (rivaroxaban) in a patient with VTE and IBD.

In terms of surgical recommendations, VTE is not an indication for an invasive procedure and despite a very limited experience colectomy per se seems not to be able to protect from recurrent thromboembolic events.

CONCLUSIONS

We presented a case of IBD complicated with DVT as extraintestinal manifestation of the disease with the aim of raising awareness of the thrombotic risk in these patients. Considering that patients with IBD are at high risk of both VTE and gastrointestinal bleeding, we highlighted the importance of accurately assessing the duration of anticoagulant therapy. The latest guidelines mention that in the treatment and secondary prevention of VTE, NOACs have comparable efficacy to VKAs, with a more favorable safety profile, but it is also stated that there is no direct evidence for NOACs use in IBD patients yet.

ELECTROSPUN NANOFIBER ORIENTATION INFLUENCES WOUND CLOSURE

Nanofibers resemble the natural extracellular matrix of the human body. Furthermore, polymer nanofibers provide an ideal environment for wound healing. A recent study aimed to evaluate the pure topographical effects that an underlying scaffold material may have on fibroblast behaviour in a novel *in vitro* wound model, which included poly-ε-caprolactone scaffolds with different nanofiber alignement. A stencil based wound assay with L929 murine fibroblasts was used to study the closure of circular wounds over time. Triggering fibroblast migration into the wound accelerates the remodeling of the dermis. Cell viability, morphology and mobility – in fact a combination of proliferation and migration, since both occur during the natural wound healing process - were assessed. The study emphasizes the important effect of orientation on increasing cell mobility, polarization and elongating cell morphologies compared to random fiber scaffolds (Ottosson M, Jakobsson A, Johansson F. Accelerated Wound Closure - Differently Organized Nanofibers Affect Cell Migration and Hence the Closure of Artificial Wounds in a Cell Based *in vitro* Model. *PLoS ONE* 2017; 12(1): e0169419. doi:10.1371/journal.pone.0169419).

COMPARATIVE MORPHOLOGICAL AND MORPHOMETRICAL ANALYSIS OF TWO THYMOMA CASES (Abstract): Thymoma is a primary tumor of the thymus epithelial cells and one of the most common neoplasms in the anterosuperior mediastinum, especially in middle-aged or older adults. There were some difficulties in thymoma diagnosis due to high variability of the morphological thymoma aspects. WHO 2004 morphologic classification reached a kind of consensus of the morphological thymoma types and established a correlation with prognostic factors. **Aim:** The aim of this study was to assess morphologically and morphometrically the two thymoma specimens for searching prognosis according with atypical features and variable invasive character. **Material and methods:** The study included 2 thymoma cases, one AB and the other B1 type, both in adults, operated for mediastinal tumoral masses. Surgery specimens were processed for histological examination. Qualitative and quantitative assessment of thymoma specimens was applied. **Results:** The study reveals various histological aspects and cytological measurement results explaining different invasiveness features in the two thymomas. The two thymoma types show a close relationship to blood vessels. **Conclusions:** Usually, the current state of the art in thymoma diagnostic defines invasion, both clinically and histologically. The morphometrical analysis, rarely used in clinical practice, could be a useful tool in prognosis assessment and offer an evolutive behavior of the tumor. **Keywords:** THYMUS, THYMOMA, MEDIASTINUM.

Thymic epithelial neoplasms are usually seen in the fourth and fifth decades of life (1, 2). Thymoma is a primary mediastinal neoplasm arising from or exhibiting differentiation toward thymic epithelial cells, typically with the presence of non-neoplastic lymphocytes (3, 4). Thymomas can be classified as benign or malignant (5). Cytologically benign thymomas are of three major types, such as lymphocyte rich, epithelial cell rich, and spindle cell type or according with their architecture as cortical, medullary, and mixed. Thymomas that are cytologically malignant are uncommon, having as a hallmark a significant cytological atypia. The local spreading feature characterizes the invasive tumors (6). We hereby present two thymoma cases with different morphological and morphometrical features. In this article, we describe pathologic features of thymomas and discuss these disease entities in terms of classification and staging evalua-

tion, in which radiology plays a crucial role. The prognosis assessment for thymic masses is necessary, as well. Morpho pathologically, atypia, mitotic activity and invasiveness are histological features used in tumor prognosis assessment.

MATERIAL AND METHODS

We present two patients, who underwent tumor excision to treat surgically the thymomas, one in 2008 and the other one in 2010, both having myasthenia gravis. We described and assessed the histological characteristics of the two thymomas, and between thymoma types and cell variables.

Morphology assessment was made with an optical microscope (Olympus CX41). The measurements were analyzed with a color image analysis system: Quick PHOTO MICRO 3.0. We studied the tumor histological structure and cytology by using usual and specific (hematoxilin eosin, elastic von Gieson, and Gordon Sweet for reticulin) stains.

Quantitative morphometry was performed by appreciation of the ratio between lymphocytes and epithelial cells, micro vessel density and nuclear area of the epithelial cells. The measurements were expressed in mean values and frequencies.

RESULTS

Two biopsies from mediastinal masses were performed. Histopathological examination revealed features of thymoma. The results of histological and cytological analysis varied in few points.

In AB thymoma, surgical biopsy showed a nodular encapsulated tumor having 2 points of capsular infiltration (fig.1, a, b). Cytologically, we found a mixture of variable proportions of lymphocyte-poor (fig.1, c), lymphocyte rich areas (fig.1, d) and discrete intermixed foci. Lymphocyte deprived areas were composed from spindle epithelial cells with few lymphocytes. Epithelial spindled to oval cells were essentially the same as those of type A, having bland nuclei, medium sized to large and round to oval.

Morphometrically, tumoral area was composed from a dual population of cells with a lymphocyte predominance of 71, 52%. Lymphocyte to epithelial cell ratio was of 1.8. Tumoral epithelial cells had an average nuclear area of 45.3 μm2. All these morphological features are common in AB thymoma. Angiogenesis was another morphological feature of the tumor. We found an average of 3 micro vessels on HPF (HE, x400).

In B1 thymoma (fig.2, a), morphological analysis showed a multinodular tumor with a thick capsule and an area of infiltration with involvement of the adjacent fat tissue. The septa had different thicknesses.

Morphologically, we emphasized zones resembling with cortical areas composed from lymphocytes with inconspicuous epithelial cells (fig.2, b). In lymphocyte, rich-areas we saw densely packed (fig.2, c), small lymphocytes. Epithelial cells had nuclei ranging from medium sized to large, with nucleoli varying from inconspicuous to prominent. Epithelial cells ranged from infrequent to occasional Hassall corpuscles. Medullary foci appeared as circumscribed round pale zones due to lose packing of lymphocytes (fig.2, d).

Morphometrically, we identified the same dual cell population, with two thirds (2/3) or more small lymphocytes from entire cell mass. The lymphocyte to epithelial cell ratio was of 2.53. The most epithelial cells were small with polygonal shape and an average nuclear area of 21μm2. Angiogenesis was greater than in AB thymoma, represented by 4 vessels on HPF (HE, x400).

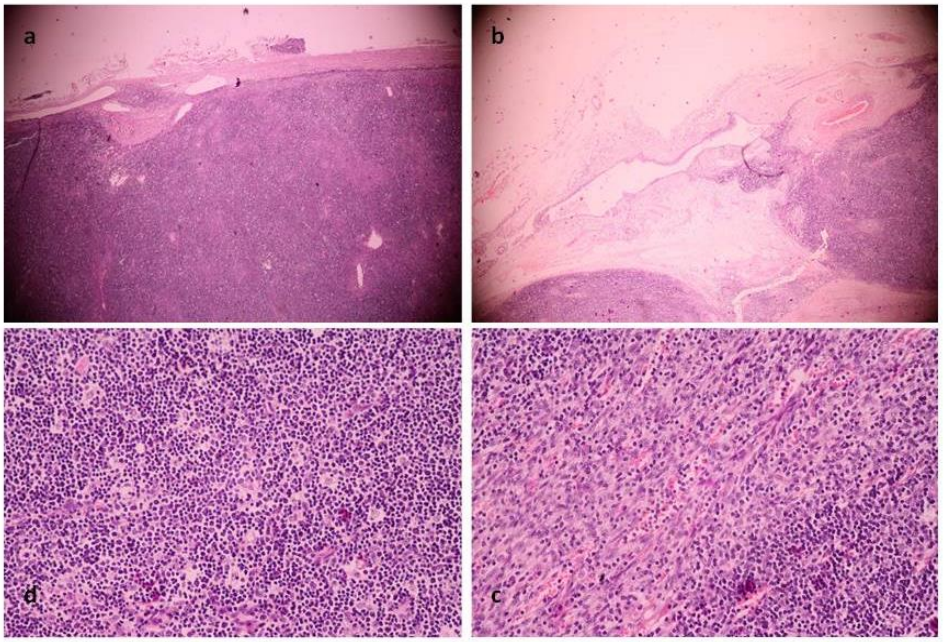

Fig. 1. Thymoma AB. a, b-foci of capsular infiltration (HE, x4); c-lymphocyte-poor area (HE, x40); d-lymphocyte-rich area (HE, x40).

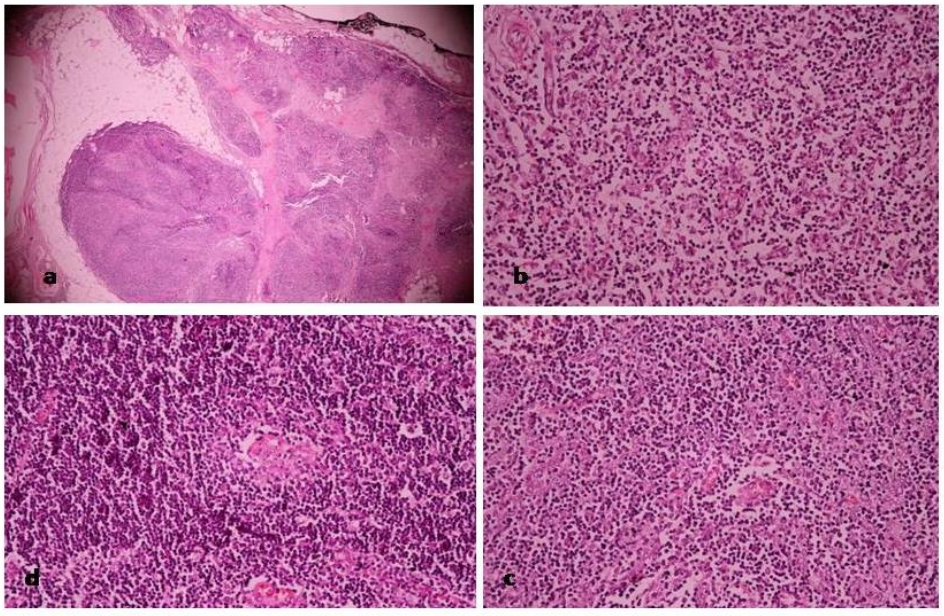

Fig. 2. Thymoma B1. a-area of fat tissue infiltration (HE, x4); b-lymphocyte rich-area (HE, x40); c-densely packed, small lymphocytes (HE, x40); d-loose packing of lymphocytes (HE, x40).

Morphometrically, we found different results between the two thymomas, according with epithelial cell sizes and shapes and their proportions reported to lymphocytes, all these distinctive features explaining differences in tumor invasiveness.

Despite angiogenesis study results are not too different; it may explain different degrees of malignancy among thymic epithelial tumors.

According with pathological stage (i.e., as defined after resection), both encapsulated tumors were in IInd stage of evolution, the first with microscopical invasion through the capsule (IIa stage for AB thymoma) and the second with invasion into surrounding fat (IIb stage for B1 thymoma).

DISCUSSION

Thymoma is a rare primary tumor of the epithelial cells of thymus and the most frequent tumor of the anterosuperior mediastinum. Its incidence increases with age (70% of cases are observed in patients past the age of 40) (7).

Distinctive features reminiscent of the normal thymus make the pathological diagnosis of thymoma easy in most cases. A fibrous capsule surrounds the tumor and sends thick, fibrous septa, dividing the tumor into well-demarcated lobules.

Microscopically, there is a distinctive dual cell population, including lymphocytes, small with dark nuclei, and epithelial cells, larger and lighter (1).

Quantitatively, the ratio between lymphocyte and epithelial cell varies widely. Thymomas are often classified according to the relative ratio of cells between predominantly lymphocytic, mixed epithelial–lymphocytic, and predominantly epithelial. In 40% of cases the tumors are predominantly lymphocytic, in 20% they are mixed and the rest are predominantly of epithelial type. The mean nuclear area increased significantly in the increasing order of noninvasive thymoma and invasive thymoma. The morphological and morphometric results demonstrated a significant difference in degree of malignancy between non- invasive and invasive thymomas. Cornea R shows a significant increase in the number of micro vessels in the temporal area, regardless the histological type of the tumor. So, in patients with thymic epithelial tumors, there appears to be a significant correlation between tumor angiogenesis and invasiveness (8).

The epithelial cells represent the neoplastic component of thymomas. They are typically round or oval, but sometimes have a spindle-shaped nucleus, which may represent the predominant cell in about 5 to 12% of thymomas, justifying the term “spindle cell thymoma,” which tends to grow more slowly. The lymphocytes are not considered neoplastic and, as in the normal thymus, are constituted mainly of T cells in various stages of maturation (1).

The clear majority of thymomas do not present considerable atypia or anaplasia. There are no reliable histologic features of “malignancy” for thymomas. The malignant behavior of a thymoma is indicated by microscopical or macroscopically invasion of the tumor capsule or of surrounding organs or by the presence of metastasis. In 90% of cases, they are well encapsulated and multilobulated, while in 10% of cases, the rupture of the capsule and invasion to the adjacent tissues are observed. About 30 to 40% of thymomas are invasive. On the other hand, a well-encapsulated thymoma may, on occasion, recur years after surgical resection (3).

It was recently postulated that thymomas may be further subdivided into those with cortical, medullary, and mixed differentiation, reflecting the anatomy of the normal thymus (2).

Cortical thymomas contain large epithelial cells with vesicular chromatin and prominent nucleoli, whereas medullary thymomas show oval to spindle-shaped epithelial cells with dispersed chromatin and inconspicuous nucleoli. Mixed thymomas contain both cortical and medullary components. Medullary and mixed thymomas appear to follow a more benign course than cortical ones. They show a lower incidence of invasiveness, lower recurrence rate, and better survival, even when capsular invasion is present. This classification has also been correlated with the size of epithelial cell nuclei using morphometrical analysis (3).

The thymomas behavior is unpredictable. The stage of the tumor at the time of diagnosis and the adequacy of the surgical excision are among the factors that influence the outcome of these tumors. The presence of clinical symptoms, large tumor size, local invasion or metastases at the time of the surgery, and predominant epithelial features are poor prognostic factors (9).

A multimodality approach that includes surgery, chemotherapy, and radiation therapy is suggested for treatment. Surgery is the mainstay of the treatment. However, complete resection is generally impossible or not feasible at diagnosis because of local invasion of important structures and metastasis (3).

The new WHO classification seems to correlate with invasiveness. The proportion of invasive thymomas was higher in B1 cases than in AB cases as in literature reports (Type B1, 69.1% comparing with Type AB, 47.3%) (10).

CONCLUSIONS

In our study, both thymoma types presented in a low stage of evolution. AB thymoma very rarely recurs while B1 thymoma may be sometimes aggressive. We noted both thymoma types show a close relationship to blood vessels. In our opinion, the micro vessel density is associated with thymoma invasiveness, and the higher radiotracer fixation may be due to increased angiogenesis. The histological prognosis assessment of these enlarged mediastinal masses is necessary, because thymomas could be sometimes aggressive tumors.

DIFFERENT VANCOMYCIN-INTERMEDIATE *STAPHYLOCOCCUS AUREUS* PHENOTYPES SELECTED FROM THE SAME ST100-HVISA PARENTAL STRAIN

The aim of this study is to characterize the factors related to peptidoglycan metabolism in isogenic hVISA/VISA ST100 strains. Recently, we reported the increase in IS256 transposition in invasive hVISA ST100 clinical strains isolated from the same patient (D1 and D2) before and after vancomycin treatment and two laboratory VISA mutants (D23C9 and D2P11) selected from D2 in independent experiments. High performance liquid chromatography-mass spectrometry (HPLC-MS) analysis of peptidoglycan muropeptides showed increased proportion of monomeric muropeptides and a concomitant decrease in the proportion of tetrameric muropeptide in D2 and derived mutants when compared to the original strain D1. In addition, strain D2 and its derived mutants showed an increase in cell wall thickness with increased pbp2 gene expression. The VISA phenotype was not stable in D2P11 and showed a reduced autolysis profile. On the other hand, the mutant D23C9 differentiates from D2 and D2P11 in the autolysis profile, and pbp4 transcription profile. D2-derived mutants exhibited differences in the susceptibility to other antimicrobials. Our results highlight the possibility of selection of different VISA phenotypes from a single hVISA-ST100 genetic background (Sabrina Di Gregorio, Silvina Fernandez, Arabela Cuirolo, Olivier Verlaine, Ana Amoroso, Dominique Mengin-Lecreulx, Angela Famiglietti, Bernard Joris and Marta Mollerach. Different Vancomycin-Intermediate *Staphylococcus aureus* Phenotypes Selected from the Same ST100-hVISA Parental Strain, Microbial Drug Resistance 2017; Vol. 23, Issue 1: 44-50).

WEIGHT STATUS AND QUALITY OF LIFE IN INFLAMMATORY BOWEL DISEASES (Abstract) The relationship between WEIGHT status and inflammatory bowel disease (IBD) is incompletely elucidated. Until recently, obesity among IBD patients was rarely found. However, in the past two decades the prevalence of obesity was rising in IBD patients. On the other hand, nutritive deficiencies and underweight status are part of the clinical manifestations of IBD and it is most commonly found in CD patients compared to UC patients. Both IBD and obesity can cause a negative impact on quality of life (QoL). **Aim:** to assess BMI in patients with IBD and quantify their QoL based on BMI. **Materials and methods:** We conducted a prospective study, over a period of 35 months (October 2011 - September 2014) that included 254 patients diagnosed with IBD (187 patients - UC and 67 CD). Disease activity was assessed by UCDAI/CDAI score. Weight status was quantified by BMI that classifies patients into four categories: underweight, normal weight, overweight and obesity. QoL was determined by the IBDQ-32 (Inflammatory Bowel Disease Questionnaire). **Results and discussion:** BMI ranged from 15.3 to 37.6 kg/m^2, with a mean significantly higher in the UC group compared with CD group (24.19 ± 3.60 *vs.* 22.04 ± 4 09 kg/m^2) (p = 0.001). The frequency of obesity was very low (4.13%). 25.96% of the patients were overweight, but frequency distributions show a significantly higher proportion with a high degree of overweight status in UC patients, while in CD patients we found a higher frequency of underweight status (p = 0.001). IBDQ-32 score values ranged from 66 to 207, with an average of 135.82. IBDQ-32 score was directly correlated with BMI, 13.8% of UC patients presented with higher scores of IBDQ-32 associated with higher BMI (p = 0.059) and in those with CD, 23, 6% were registered this association (p = 0.055). **Conclusions:** The results of our study cannot support that overweight status QoL of IBD patients, sooner we can say that the absence underweight status and obesity was associated with a better QoL. **Keywords:** INFLAMMATORY BOWEL DISEASES, QUALITY OF LIFE, WEIGHT STATUS.

The inflammatory bowel diseases (IBD) are chronic disorders whose etiology is yet to be clarified. This is the result of the interactions between genetic, immunologic and environmental factors (1). The IBD prevalence has increased over the last decades, especially in developing countries and in the areas characterized by high socio-economic development (2). This led to the hypothesis per which the emergence

and development of IBD is influenced by the changes underwent by changing food habits and the lifestyle associated with modern life (2).

The prevalence of obesity increased in parallel with the increase in IBD, suggesting the involvement of common environmental factors in the development of these disorders (3).

Until recently, the prevalence of obesity among the patients with IBD was low; nevertheless, the prevalence of obesity has increased in patients with IBD (4).

From another perspective, nutritional deficiencies and the underweight status have started to be part of the clinical picture of IBD, being more often met in Crohn's disease (CD) compared with ulcerative colitis (UC) (4). Starting from this data, we assessed the weight status in patients with IBD and we quantified the quality of life based on this index.

MATERIAL AND METHODS

1) We conducted a prospective study, carried out during 35 months (1 October 2011 - 30 September 2014). The sample consisted of 254 patients diagnosed with IBD (187 patients with UC and 67 patients with CD) who were attended at the Institute of Gastroenterology and Hepatology within the "Sf. Spiridon" County Clinical Emergency Hospital Iași.

2) The UC, respectively IBD diagnosis were supported by complete hematologic, biochemical tests, endoscopic and imagery examinations, as well as histopathological confirmation. The activity of the disease was quantified by means of the UCDAI/ CDAI score.

3) The weight status was quantified by the body mass index (BMI). This is a scientific official indicator for computing the ideal body weight for a given height. BMI is useful in establishing the weight group in which a person fits, classifying the weight status into four categories: underweight, normal weight, overweight and obesity,

4) The quality of life was assessed with the IBDQ-32 questionnaire (Inflammatory Bowel Disease Questionnaire). This is one of the most widely used questionnaires in QoL assessment. The questionnaire comprises 32 questions organised into four fields: gastrointestinal symptoms (diarrhoeal stoles, abdominal pain, rectorragia, rectal tenesmus), systemic symptoms (fatigue, sleep disorders), emotional functions (depression, irritability, anger, sexual activity) and social functions (absenteeism, affected social status). The responses in the questionnaire were graded from 1 (the worst) to 7 (the best). The total score is comprised in the range 32-224. Moreover, we computed the sub-scores for each distinct field (emotional functions: 12-84, gastrointestinal symptoms: 10-50, systemic symptoms: 5-35 and social functions: 5-35). The lower this score is, the more affected the HRQoL.

RESULTS

The study sample included 254 patients diagnosed with IBD and distributed into two groups:

- Group A - 187 patients with UC
- Group B - 67 patients with CD

The patients' distribution into the two samples is graphically presented in fig. 1.

BMI varied in the range 15.3-37.6 kg/m^2, registering an average value significantly higher in the group of patients with UC (24.19±3.60 *vs.* 22.04±4.09 kg/m^2) (p=0.001), classifying though the study groups as normal weight (fig. 2).

Of the total 254 subjects investigated, it can be noticed that the number of obese

patients was very low, with only 4% of the patients obese.

On the other hand, 31.9% of the cases were overweight, but the frequency distributions highlight a significantly higher ratio, with a high degree of the overweight status in the patients with UC, while in the patients with CD it can be noticed a higher frequency of the underweight status (p=0.001), (fig. 3).

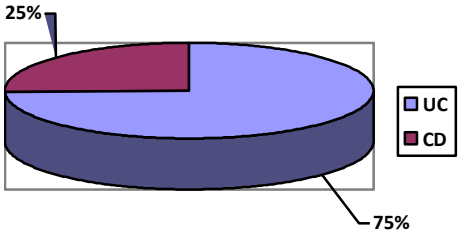

Fig. 1. - Structure of the studied sample

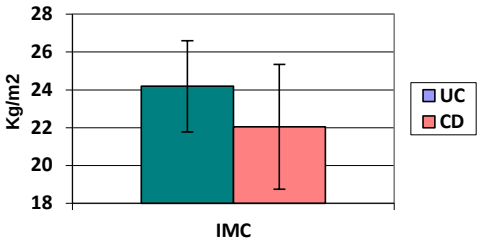

Fig. 2. The average values of BMI by study sample.

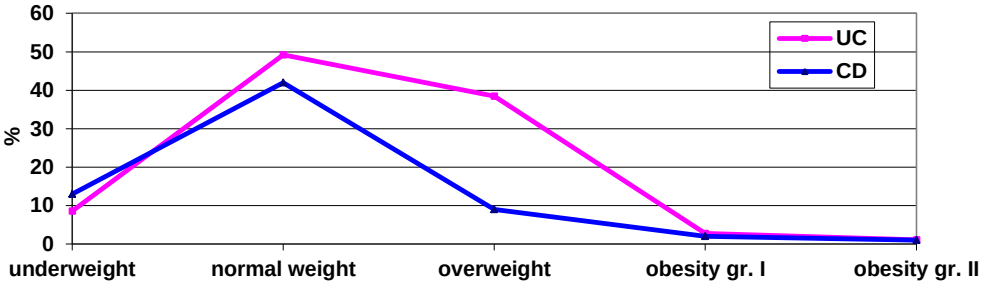

Fig. 3. Distribution of cases based on weight status.

The results of the present study could account for the pro-inflammatory role of the excessive fatty tissue in the patients with UC. Nevertheless, due to the low number of obese patients in the studied sample, we cannot support this hypothesis with certainty.

On the other hand, the higher frequency of the underweight status in CD confirms the fact that its mechanisms are more frequently met among patients with CD.

There are studies which demonstrated that malnutrition impacts the quality of life in patients with IBD. On the other hand, obesity also has a negative impact on the quality of life. Stating from this data, we assessed the quality of life in patients with IBD based on BMI.

In the studied cases, the values of the IBDQ-32 score varied from 66 to 207, with an average value of 135.82.

In the studied samples, the IBDQ-32 total score was directly correlated with BMI, 13.8% of the patients with UC presenting increased values of the total IBDQ-32 associated with increased BMI values (p=0.059); in the sample of patients with CD, 23.6% presented this association (p=0.055), (fig.4).

Since the overweight status was predominant in both studied samples, we can-

not support the hypothesis that this status contributed to improving the quality of life in the patients with IBD; we could rather infer that the absence of underweight and obese status was associated with improved quality of life.

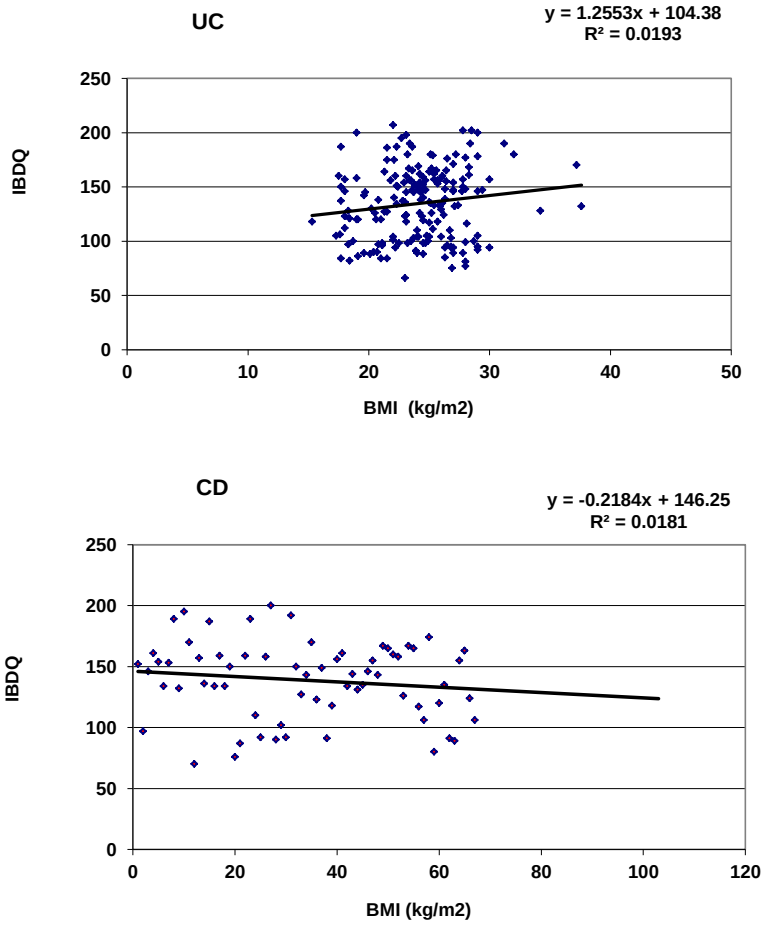

Fig. 4. Correlation between the IBDQ-32 score with BMI, by study samples.

We should notice the fact that among the patients with CD, the correlation of BMI with the IBDQ-32 score registered a higher percentage compared to the sample of patients with CD (23.6% *vs.* 13.8%). Since the frequency of the underweight status in the group of patients with CD was higher, this fact emphasizes the positive impact of an optimal nutritional status in the case of patients with CD.

The IBDQ-1 subscore quantified the impact of the gastrointestinal symptoms on the quality of life as being represented by the result of 10 of the 32 questions included in the IBDQ-32 questionnaire. Its values varied from 14 to 50, with limits comprised in the range 10-50. The patients with CD presented a significantly lower average

value compared to the patients with UC (29.78 *vs.* 33.64; p=0.001).

The analysis of the data assessing the sub score of the gastrointestinal symptoms (IBDQ-1), revealed a direct correlation of this subscore with BMI (fig. 5).

Only 12.7% of the patients with UC presented high values of the IBDQ-1 score associated with high BMI values (p=0.083), while in the CD sample, 27.1 of the patients registered this association (p=0.026). These results are like the total IBDQ-32 score. Again, it results that the gastrointestinal manifestations are reduced in patients with normal weight or overweight, in the absence of the underweight or obesity.

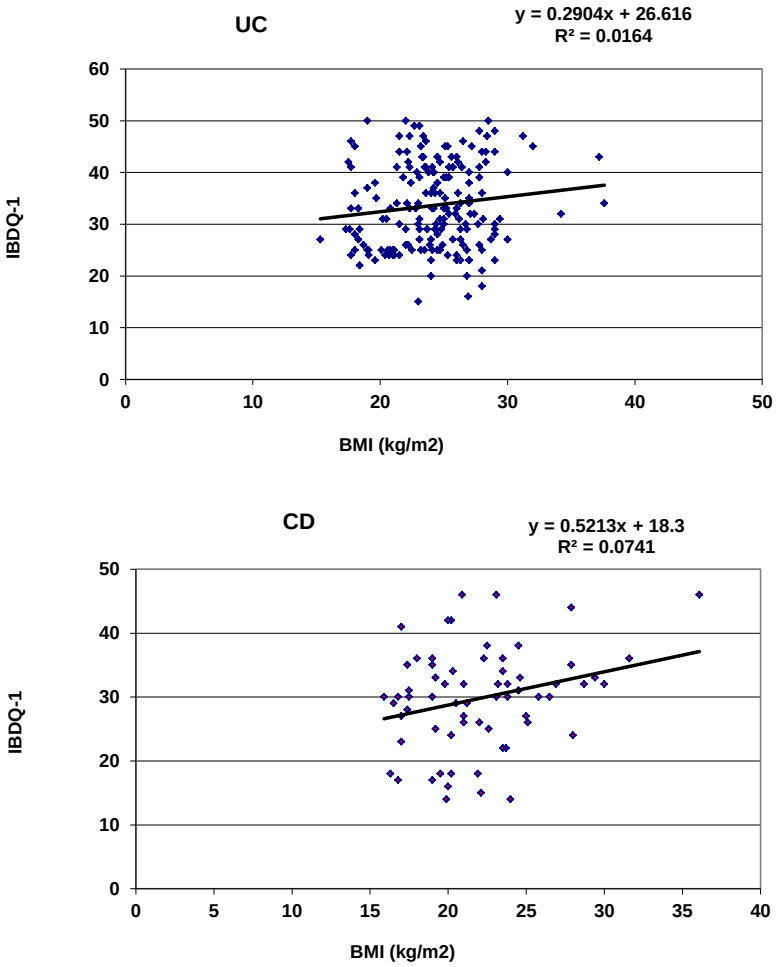

Fig. 5. Correlation between the IBDQ-1score with BMI, by study samples.

5) The IBDQ-2 subscore is the result of 5 of the 32 questions included in the IBDQ-32 questionnaire, with values in the range 5-35. This subscore quantified the impact of systemic symptoms - represented by chronic fatigue, energy level, general state of illness, quality of sleep and lack of energy - on the quality of life in patients with IBD.

In the study sample, the IBDQ-2 score varied from 5 to 35, without recording significant differences of the average values between the two disorders (22.50 *vs.* 21.24; p=0.256).

To assess the correlation between BMI and the systemic manifestations in IBD, we analyzed the average score of the systemic symptoms (IBDQ-2). The analysis of this data highlighted the presence of a significant correlation with BMI. Both in the patients with UC and in those with CD, high BMI was associated with lower systemic symptoms.

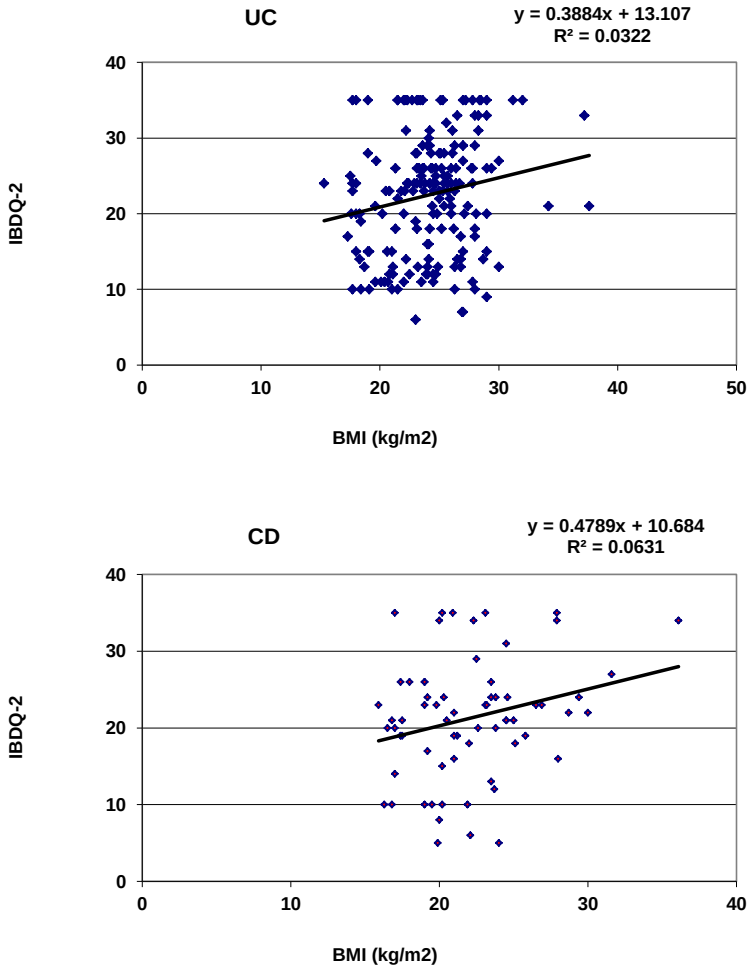

Fig. 6. Correlation between the IBDQ-32 score with BMI, by study samples.

We notice the fact that approximately 18% of the patients with UC (p=0.014) and 25% of the patients with CD (p=0.041) registered increased values in the IBDQ-2 score associated with increased BMI values (fig. 6). In both studied samples, the lowest values recorded for the score of the systemic symptoms were observed in underweight

patients, but were not significant from a statistic point of view. These results confirm once again the negative effect of underweight status on patients with IBD.

6) The IBDQ-3 subscore is the result of 12 of the 32 questions included in the IBDQ-32 questionnaire, with values in the range 12-84. This subscore quantified the impact of IBD on the patients' emotional functions (frustration, impatience, agitation, irritability, worries, depressive states, anger, (irrational) fear of being diagnosed with cancer, crying, sexual activity, anxiety, happiness).

In the studied sample, the IBDQ-3 values varied from 34 to 84, registering an average value significantly higher in the patients with CD.

About the emotional functions assessed through the IBDQ-3 subscore in both samples, they were not influenced by the weight status. It can be noticed, however, then only 10% of the patients with UC (p=0.153) and 18.6% of the patients with CD (p=0.133) presented high values of the IBDQ-3 score associated with increased BMI values (fig. 7). Thus, for both disorders, it appears that BMI did not influence the emotional functions.

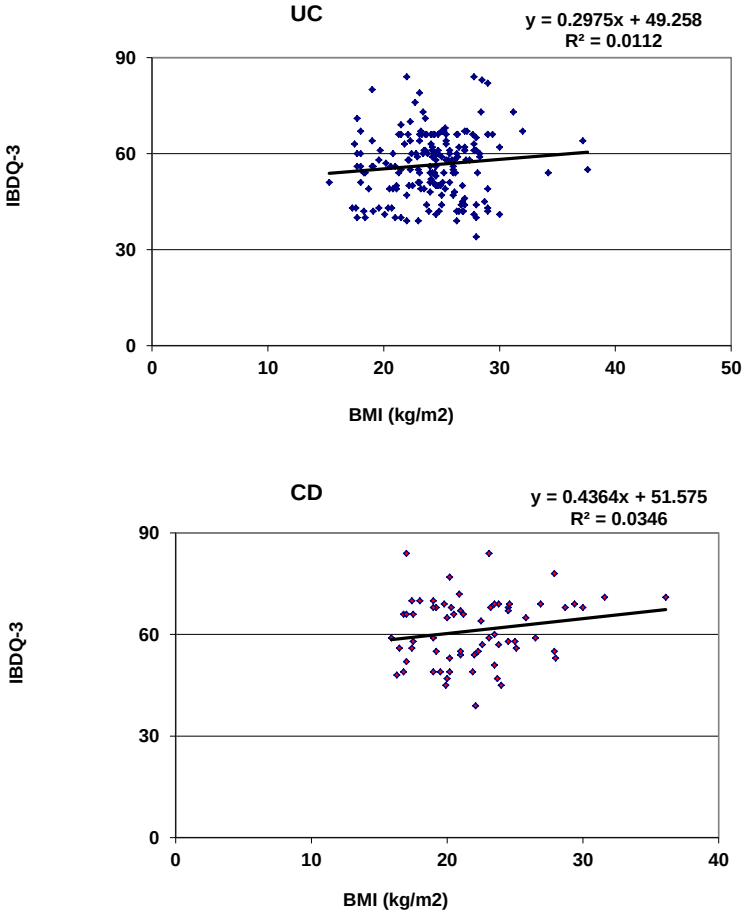

Fig. 7. Correlation between the IBDQ-3 score with BMI, by study samples.

Nevertheless, the patients with UC presented lower values of the IBDQ-3 subscore compared to the patients with CD, irrespective of the BMI. Because the emotional functions in the patients with UC were significantly more affected compared to the patients with CD, as previously mentioned, we consider this aspect to be a particularity of the study sample.

7) The IBDQ-4 subscore is the result of 5 of the 32 questions included in the IBDQ-32 questionnaire, with values in the range 5-35. This subscore quantified the impact of IBD on the social functions (absenteeism, social commitment, leisure and participation in certain social events).

In the studied sample, the values of the IBDQ-4 subscore varied from 5 to 35, registering a significantly lower average value in the patients with UC (22.27 *vs.* 26.21; p=0.001).

About the social functions, none of the samples revealed statistically significant differences based on BMI. In the case of the patients with UC, the score of the social functions (IBDQ-4) did not correlated with BMI (p=0.085). Additionally, in the case of the patients with CD, BMI was not associated with damage in the social functions either (p=0.090).

However, lower values of the IBDQ-4 subscore are noticed in the patients with UC compared with the patients with CD (fig. 8).

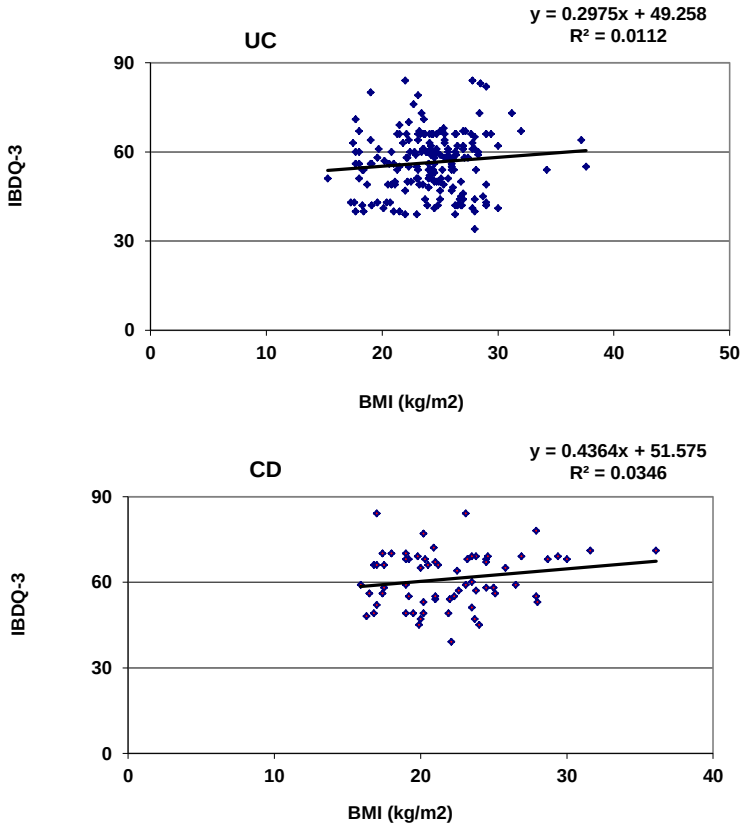

Fig. 8. Correlation of the IBDQ-4 score with BMI, by study samples.

To conclude, both in the patients with UC and in those with CD, high BMI was associated with higher quality of life, an aspect noticed in a higher ratio in the sample of patients with CD. The average IBDQ-32 total score and its 4 subscales were slightly higher in the patients with obesity in both study groups ($p>0.05$).

Based on these results, we cannot support the hypothesis that the overweight status improved the quality of life in patients with IBD; we could rather infer that the absence of underweight and obese status was associated with improved quality of life. Moreover, although the percentage of obese patients included in the study was lower, their quality of life was higher, indirectly refuting the presence of severe forms of IBD, respectively the pro-inflammatory role of the fatty tissue.

DISCUSSION

In the study presented above, most patients had normal weight. Of the total 254 subjects investigated, 4% were obese and 31.9% overweight. In the UC sample, we noticed a significantly higher ratio of overweight patients (38.5%), which can confirm the pro-inflammatory role of the excessive fatty tissue in patients with UC. On the other hand, although most patients with CD had normal weight (62.7%), as also shown in the specialized literature, the frequency of the underweight status was high compared to the sample of patients with UC ($p=0.001$). The results of the present study confirm the fact that for CD, the causes and mechanisms of the underweight status are more frequently met compared with the patients with UC.

The studies in the literature have shown that specific nutritional deficiencies and the underweight status are more frequent among patients with IBD (5).

In some studies, weight loss was met in 70-80% of the in-patients with IBD and in 20%-40% of the outpatients with CD. The prevalence of malnutrition was low among the patients with UC, but nutritional deficiencies can shortly occur in these patients as well, especially during the disease activity periods (4).

Malnutrition is often associated with acute or severe gastrointestinal disorders, having an impact both on their morbidity and mortality (5). Damaged nutritional status also impacts muscular strength, which eventually determines the decrease in the functional status. Moreover, malnutrition was associated with decreased functional state and damage of the immune system (5).

On the other hand, the prevalence of obesity increased over the last decades, being currently considered pandemic (4). While obesity is not frequently met in IBD, several studies focused on the increase in its prevalence among these patients (6, 7), being more frequent in patients with CD compared to patients with UC. A recent study carried out in Scotland showed that 18% of the patients with IBD are obese (BMI > 30 kg/m^2), compared to 23% of the general population in Scotland.

Although IBD are not considered "classic" comorbidities of obesity, these two entities have a cause-effect relation and are associated with increased inflammatory reactions (8). There are studies supporting the hypothesis that obesity accounts for the increase in inflammatory cytokines, leading thus to IBD development (9). Moreover, several studies have shown that morbidity increased among the obese patients with IBD, including the rate of hospitalization, perianal complications and the disease activ-

ity periods (10, 11). Other published data indicated the fact that the obese patients with IBD are more prone to complications in case of surgical intervention, and that these complications were determined especially by obesity comorbidities (12).

As far as the relationship between the nutritional status and the quality of life are concerned, research has sported the existence of a direct correlation between malnutrition and decreased quality of life, especially in older in-patients (13, 14), oncologic patients (15) and hemodialyzed patients (16, 17).

A study assessing the quality of life of patients with gastrointestinal disorders and malnutrition conducted in Germany demonstrated that malnourished patients with IBD presented lower QoL scores (18).

On the other hand, obesity generally has a negative impact on the quality of life (438).

CONCLUSIONS

In our study, BMI correlated significantly with the score for systemic symptoms (IBDQ-2). Higher BMI was associated with higher QoL scores. 25 % of the patients with CD (p=0.041) and 17.9% of the patients with UC (p=0.014) presented high values of the IBDQ-2 score associated with increased BMI values.

Based on these results, we cannot support the hypothesis that the overweight status improved the quality of life in patients with IBD; we could rather state that the absence of underweight and obese status was associated with improved QoL.

NEWS

PREDICTION OF POSTOPERATIVE RENAL IMPAIRMENT USING A NEW URINE MARKER

Prognosis of cases in cardiac surgery is influenced by early detection of postoperative complications such as acute renal injury (ARI). Determination of creatinine serum levels is simple and inexpensive but can delay ARI diagnosis. The researchers of Department of Thoracic and Cardiovascular Surgery, University Medical Center Göttingen, Germany evaluated the importance of determining urinary neutrophil gelatinase-associated lipocalin (uNGAL) for predicting ARI occurrence after cardiopulmonary bypass (CPB). NGAL is a protein expressed by urothelial cells of the renal tubular system and it appears in the primary urine to 60–120 min after stress induction. The study included 81 adult patients with CBP without morphological or functional renal alterations. uNGAL level was determined in seven time points (before, during and after CBP). Also, were measured serum creatinine levels and glomerular filtration rate and was evaluated renal function per the Acute Kidney Injury Network criteria. The results showed that NGAL values increased after 120 minutes from the start of CPB and have remained elevated after CBP. Results of the study did not establish a correlation between uNGAL level and duration of CPB nor between uNGAL expression and occurrence and severity of ARI. The researchers suggested that "biomarker uNGAL failed to predict the onset and the severity of acute renal failure after cardiac operations" (Friedrich MG, Bougioukas I, Kolle J, Bireta C, Jebran FA, Placzek M, Tirilomis T. NGAL expression during cardiopulmonary bypass does not predict severity of postoperative acute kidney injury. *BMC Nephrol* 2017; 18(1): 73. doi: 10.1186/s12882-017-0479-8).

ETHNOBOTANICAL AND CANNABIS DRUG USE: A STEP BETWEEN DANGER AND PLEASURE (Abstract): **Aim:** The study aimed to identify the risk factors and the particularities of ethnobotanicals and cannabis users who needed medical care in the Emergency Department of the „Sf. Spiridon" County Hospital. **Material and methods:** Retrospective study conducted over a period of 18 months (January 1, 2015- June 30, 2016). This study included all patients who presented to the E.D. after drug (cannabis and ethnobotanicals) consumption. The variables studied for creating the consumer profile were sex, age, social background, method of consumption, clinical and laboratory changes. **Results and discussion:** The study included 153 patients brought to hospital by ambulance (71.89%) for cannabis or ethnobotanical poisoning. Most patients were males (92.15%) from urban areas (75.97%), aged between 18 and 24 years (52.28%). At the time of admission to ED 96.07% of them needed medical care for consumption of ethnobotanicals through various methods and only 3.92% were brought to hospital for cannabis or marijuana use. For 61.70% of patients, curiosity was the reason behind their addiction. Toxicology testing (qualitative urine analysis) was useful in identifying the presence of tetrahydrocannabinol(THC) or a combination of THC and barbiturates, benzodiazepines, opioids in 26.53% of ethnobotanical and 66.67% of cannabis users. **Conclusions:** In Romania, the most commonly used drugs are cannabis followed by ethnobotanical products. For a while, ethnobotanical products were falsely considered as risk-free, but they contain dangerous substances with devastating effects, which, unless treatment is initiated immediately, can lead to death. **Keywords**: CANNABIS USE, ETHNOBOTHANICALS, POISONING.

Drugs have been known ever since antiquity, but their use has changed throughout history. In the beginning, they were used in medical and religious practice, being nowadays a source of expensive pleasure for teenagers and young adults (1).

In 2008 cannabis was the most widely used illicit drug in Romania. In 2008 Romania ranks fourth among the cannabis-consuming countries after England, Germany and Holland (2, 3, 4). Starting with 2009, new psychoactive substances have been increasingly used reaching a peak in 2010. The new legislation and the media

involvement led in 2013 to a slightly reduced usage of ethnobotanicals, which came second (18 per cent) immediately after heroine (42.7 percent) and before cannabis (15.6 percent). According to the 2014 National Antidrug Agency annual report the use of the new psychoactive substances has slight increased.

In 2014, the most commonly used drug in Romania was cannabis -10 percent in Bucharest and Ilfov, 5.9 percent in Southeast Romania, 2.9percent in the Western part of the country,2.5 percent in the Northwest, 1.6 percent in the South and Centre, 1.5 percent in the Northeast and 0.4 percent in Southwest (5, 6, 7, 8, 9, 10, 11).

Per "European Monitoring Centre for Drugs and Drug Addiction", Romania ranks eighth among the cannabis-consuming European countries, after France, Czech Republic, Italy, Denmark, Poland, Austria and Portugal (12, 13).

MATERIAL AND METHODS

This retrospective study covers 18 months and includes the patients cared at the Emergency Department of the Iasi "St. Spiridon" Hospital due to the use of the new psychoactive substances or cannabinoid substance.153 patients were included in this study, represented by 141 (92.15%) male and 12 (7.85%) female. The minimum age was 18.

Variables included were: age, sex, social environment, the main cause of addiction, drug type, method and age at onset of drug use, drug-related clinical and laboratory changes.

Vulnerable patients and patients having refused toxicological analysis were not included. Information was taken from patient medical records.

Data were analyzed and statistically processed using Microsoft Excel and *SPSS 18.0* statistics software. Patients characteristics were expressed as the mean standard deviation or as a number and percentage.

RESULTS

The study was conducted between January 1, 2015 and June 30, 2016 and included 153 patients who presented at the Emergency Department of the Iasi "Sf. Spiridon" Hospital for having used ethnobotanical and/or cannabinoid substances. Sex distribution of patients did not differ from that in the statistics of the Annual Reports of the National Antidrug Agency. Thus, in our study the clear majority of cases were male, 141 (92.15%) only 12 cases (7.85%) being female. Of the patients needing medical care following the use of ethnobotanical and/or cannabinoid substances 78.57% were brought to hospital by ambulance, 71.89% of them being hemodynamically stable. A significantly smaller percentage came by their own means (20.26%).

Educational, economic, and sociocultural factors contributed to an uneven distribution by place of residence –75.97% being urban patient. Age ranged from 18 to 54 years, with most cases aged 18-24 years (52.28%). 74.50% of the patients received medical care 1-3 hours after substance use. Per statistics, most patients had consumed ethnobotanical substances (96.07%) compared to 3.92% who used cannabis and marijuana. The most commonly used delivery method was via inhalation, declared by 98.69% of the users, the remaining 1.31% preferring the administration via ingestion or injection (fig. 1).

Of the ethnobotanical substance consumers (134 males and 13 females) 63.94% claimed to be occasional users, 30.61% chronic users (5 months-13 years) and 5.44% accidental user, smoking ethnobo-

tanical cigarettes offered by acquaintances or found on the street. Of the occasional users, 61.70% declared curiosity as main reason for substance use, the remaining 38.30% mentioning pleasure as main motivation (fig. 2).

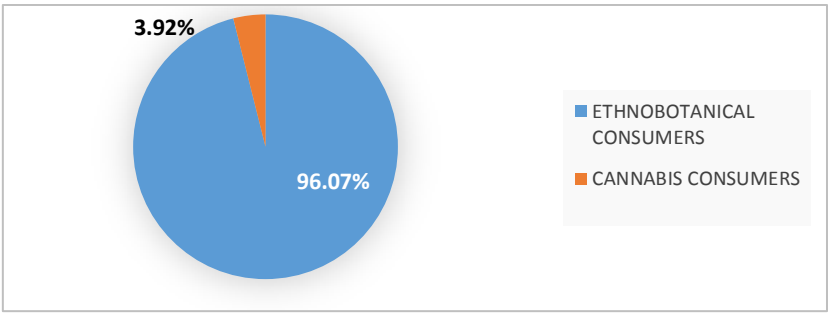

Fig. 1. Percentage distribution of used drugs

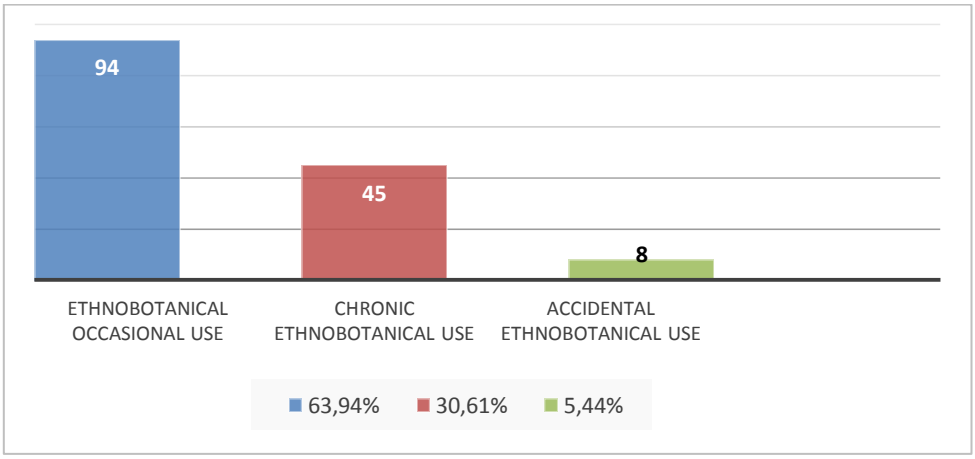

Fig.2. Patient distribution per substance use manner

Upon presentation to the Emergency Department, 11.56% of the chronic users had been admitted to substance abuse treatment and 2.72% had been treated for various psychiatric disorders at the Iasi Hospital of Psychiatry. Of the users of ethnobotanicals requiring medical care 70.06% were urban male patients (113/76.87%), aged 18-30 years (85.71%), brought by ambulance. 131 inhalation cases self-procured the ethnobotanical substance (89.11%) and 43 of them (29.25%) used ethanol as well.

Clinical symptoms included dizziness (19.04%), nausea and psychomotor agitation (18.36%), vomiting (14.28%) and palpitations (13.60%). ECG demonstrated sinus bradycardia, early repolarization, and minor right bundle branch block in 26.53% of ethnobotanical drug users. Urine toxicology testing done with the Triage Meter Pro using fluorescence for the immuno-

chemical tests performed at patient's bedside showed 26.53% patients positive for: BZO (10.88%), THC (10.20%), BAR (4.08%), APAP (2.72%), OPI (2.04%), TCA (1.36%). 7.47% of the toxicology tests could not identify the substance, although the patients declared and clinical evidence indicated ethnobotanical drug use.

The emergency physician has an extremely important role in case of overdose/intoxication where the substance, consumed amount, subsequent course and possible complications are unknown, in most such cases the doctor acting as interface between the patients in various stages of intoxication, and the hospital environment. Immediate emergency procedures are vital in such cases.

Early diagnosis and specific therapy reduce the risk of possible complications in ethnobotanical drug intoxication. History and clinical examination were thoroughly considered as they are key in diagnosing the patient with ethnobotanical drug intoxication.

Medical and scientific publications make little reference to the best treatment in cases of synthetic drug addiction. Early diagnosis and therapy are the best ways of reducing possible complications in ethnobotanical drug intoxication. There is no specific antidote or standard treatment because we have little information on the substance composition (substances being extremely varied), therefore vital signs (circulation and breathing) were stabilized first, and then the symptoms were treated.

Of the 147 patients consuming new psychoactive substances only 4.76% needed continuous follow-up at the Toxicology Clinic of the Iasi "Sf. Spiridon Hospital", the remaining 95.24% being referred to the Psychiatry Hospital (32.65%), to other hospitals (4.76%), back home (44.22%) and 13.61% left the hospital by themselves, being hemodynamically stable.

In the patients requiring medical care for cannabis and marijuana use (3.92%), aged 19-42 years, the sex ratio was like that recorded for the ethnobotanical drug users - 83.33% males. 66.67% arrived by ambulance, most patients residing in urban areas (66.67%). One patient reported cannabis cake ingestion (16.67%), 33.33% reported inhalation of cannabis and 50% inhalation of marijuana. 83.33% of the cases were occasional users. 50% of the cannabis and marijuana users reported pleasure as main reason whereas 33.33% reported curiosity as main motivation. The average time interval between inhalation and arrival at the Emergency Department was 1 to 2 hours, 83.33% of the patients being hemodynamically stable with palpitations (50%) and dizziness (33.33%).

Of the cannabis and marijuana users, 66.67% had positive urine toxicology tests in equal ratios for THC and BZO (33.33%).

The emergency department length of stay was approximately 5 hours, the vital signs being stabilized during this interval. 16.67% required hospital admission, the remaining patients being either discharged home or leaving the hospital after being stabilized.

DISCUSSION

The analysis and comparison of data provided by the National Antidrug Agency and the statistical data obtained from the present study show major differences between drug types consumed at a national level and drugs consumed in the North-East region, mainly in Iasi (5, 6).

Although during the past 8 years at national level cannabis has been the most

commonly used drug among teenagers and young adults, followed, starting with 2009, by the new psychoactive substances, most drug users in the Iasi area have been using ethnobotanical substances (96.07%), cannabis being consumed only by 3.92% (2, 3, 4, 5, 6).

The distribution by sex and area of residence is like that at the national level –the majority being male urban consumers.

Age group distribution of the study cases showed that most ethnobotanical drug users were young: 15-24 years (4.3%) with 52.38% in the 18-24 age group. Most cannabis consumers were aged 25 to 34 years (7.4%) at the general population level (4).

University students cover 29.41% of the studied population, percentage close to the one at the national level.

At the national level, 2 thirds of the ethnobotanical drug users (60% in 2014 compared to 61.2% in 2013) live in Bucharest, Iasi, Cluj, Galati.

Both cannabis and ethnobotanicals prevail in Bucharest-Ilfov (10% and 3.9%, respectively), whereas in the North-Eastern region the recorded percentages are only 1.5% and 0.8%, respectively (5, 6, 15).

Insufficient data concerning chemical composition, ingredients and possible dangerous substances used in the new psychoactive drug fabrication make more difficult the evaluation of health risks and toxicity levels. (1, 14, 15) Some drugs are combined with alcohol and other illegal drugs with dangerous side effects. Teenagers are tempted to diversify their drug consumption even if they know the risks involved by the association of illicit drugs with alcohol, tobacco, barbiturates and amphetamines (16).

Easy access and accessible prices make ethnobotanical drug intoxication an important issue. Alongside long term effects, ethnobotanical drugs are a social danger leading in time to the use of more dangerous drugs.

CONCLUSIONS

In Romania, the most commonly used drugs are cannabis followed by ethnobotanical products. For a while, ethnobotanical products were falsely considered as risk-free, but they contain dangerous substances with devastating effects, which, unless treatment is initiated immediately, can lead to death.

Data concerning chemical composition and ingredients are insufficient and these substances used among alcohol and other type of drugs can be dangerous and can lead to death of patient.

PHOTODYNAMIC THERAPY AS A PROMISING METHOD USED IN THE TREATMENT OF ORAL DISEASES

Photodynamic therapy is a innovative therapeutic method that has already been successfully adapted in many fields of medicine (e.g. gynecology, urology, dermatology) and cancer therapy. Dental medicine is also beginning to incorporate photodisinfection for treatment of the oral cavity. Photodynamic therapy consists of three elements: photosensitizer, light and oxygen. The photosensitizer has the property of selective accumulation in abnormal or infected tissues without causing any damage to the healthy cells. The antibacterial and fungicidal properties of the photosensitizer have been used to achieve better results in root canal treatment, periodontal therapy and the eradication of candidiasis in prosthodontics. Photodynamic therapy could be considered as an alternative treatment protocol in oncology, endodontics, periodontology and other fields of dentistry. (Prażmo EJ, Kwaśny M, Łapiński M, Mielczarek A. Photodynamic Therapy As a Promising Method Used in the Treatment of Oral Diseases. *Adv Clin Exp Med*. 2016 Jul-Aug; 25(4):799-807).

OPTIMAL TEACHING OF CARDIOPULMONARY RESUSCITATION IN SCHOOLS: BETTER EDUCATION, MORE LIVES SAVED (Abstract). Teaching cardiopulmonary resuscitation in Romanian schools is a joint initiative of the Acute Cardiac Care Working Group of the Romanian Society of Cardiology, the Romanian National Resuscitation Council and the Romanian Society of Emergency Medicine and Disaster. Teaching young generations to save people in cardiac arrest requires a structural approach, whose starting point is the launching of a large-scale campaign in favor of introducing the basics of cardiopulmonary resuscitation (CPR) in the school curriculum. The training stages can be set according to the principle of repetition (i.e. every two years). Teachers seem to be the best candidates for the instructor position, taking into account the knowledge and skills they acquired throughout the teacher training programs, as well as their continuous contact with the students; consequently, training teachers to become CPR instructors represents a long term investment. All acquired knowledge will implicitly spread to a secondary level (trainee's parents, relatives, etc.) and the number of individuals gaining access to CPR specific information will rise as a consequence. Entering the CPR training program should be promoted as a criterion for the accreditation and/or evaluation of primary schools, middle schools, and high schools. To begin with, this program must be implemented in Romania at first as part of the non-formal context of the special education week called *"Şcoala altfel"* ("School otherwise"). **Keywords**: RESUSCITATION, TRAINING, SCHOOL, CARDIAC ARREST.

Including basic cardiopulmonary resuscitation (CPR) in educational programs during schooling is a necessity of the modern world: with better education, more lives are saved. While in Norway, the country with the largest number of islands in Europe, CPR notions have been part of the school curriculum since 1961, an approach promoted only in 1992 as part of the European Resuscitation Council (ERC) policy (1, 2), this process has started in Romania only recently, as a result of the initiative of the Acute Cardiac Care Working Group of the Romanian Society of Cardiology,

which was also joined by the Romanian National Resuscitation Council and the Romanian Society of Emergency Medicine and Disaster ("You Can Also Save a Life!" Project) (3).

CPR in Romanian schools

Preparing a whole generation to be able to save people in cardiac arrest requires the initiation of a large-scale campaign in favor of introducing the basics of cardiopulmonary resuscitation in the school curriculum. The national impact of such an approach would be a considerable one; according to data provided by the National Institute of Statistics (2011/2012), the distribution analysis by level of education shows that of the total population of 3,823,515 individuals belonging to the school population, 673,641 are preschool children, 1,629,406 are part of the primary and secondary school cycles (1st–4th grades: 803,902 students; gymnasium 5th to 8th grades: 809,339 students, and special education classes 1st-8th grades: 16,165 students), 888,768 are in high school, 12,382 are enrolled in vocational education, 79,466 are in post-secondary education and apprenticeships, and 539,852 are in higher education (4). Therefore, the training of all these categories requires a considerable organizational effort, especially as such an approach needs to be repeated as a sequence (training–evaluation of training quality–re-training) at different stages of education. Moreover, as 55.1% of its inhabitants live in rural areas associated with poverty, Romania has the lowest level of urbanization in the European Union (by comparison, urbanization rates of our neighbor countries are: Bulgaria - 70.9%, Hungary - 67.8%) (4). These differences between urban and rural areas relate to infrastructure development, household equipment, access to public utilities, but also to a lower school instruction, limited access to forms of secondary education and a rural-urban gap in what concerns medical services (5).

A re-conceptualization of children as social actors is necessary; it is time for children to be regarded neither as "captive audience" when analyzed from the perspective of the information reception, nor as "adults in waiting" when assessing their effective participation, but as future citizens among whom altruism (the "Good Samaritan" attitude) should be encouraged (6, 7). Children are more easily motivated, they can easily learn various sequences of actions, but they obviously have a limited life experience, so they rely largely on the knowledge and guidance of teachers, who, in turn, should receive regular training in this area to avoid dilution of their knowledge (8). The young people of Romania's 2010-2020 decade are characterized by the presence of much more pragmatic values, which deserve to be brought to fruition.

In Romania, the "Good Samaritan Law" is currently in force, backed by the Law on Health Reform (Law 95/2006), which stipulates under Article 88 that "persons without medical training providing first aid on a voluntary basis, based on indications provided by a medical dispatcher or with some basic knowledge of first aid, acting in good faith and with the intention to save the life or health of a person, have no criminal or civil liability" (9). Thus, someone who wants to help can not be held liable even if something unpleasant happens to the victim.

Basic Life Support (BLS) training in schools

To meaningfully reduce the mortality in

out-hospital cardiac arrest (OHCA) cases, 15-20% of the population must know and perform BLS maneuvers (10). School is the place where such knowledge may be acquired. It is also a cost-effective and widely spread approach, as many local/ regional initiatives have proven: "ABC for life" (10), the Hampshire experience (11), the Washington experience (12), the Barcelona experience (13), or the Norwegian experience (14). However, the currently available data is still heterogeneous (15).

Optimal age for CPR training

There are studies on subjects at the kindergarten age (4-5 years) who were able to estimate the level of consciousness of a victim, whether the victim is breathing or not, to remember and dial the emergency alert service, to provide sufficient information to the dispatcher, to place the victim in the recovery position and to ensure the victim's airway permeability, skills that were maintained at a 2 months post-training examination (16). Two studies have found that children with a body mass index (17) over 15 or a minimum body weight (18) of 50 kg can correctly perform chest compressions.

The training of children in CPR must be differentiated according to age: young children involved in calling for aid, older children possibly involved in usual resuscitation maneuvers.

Optimal CPR training method

The manikin training is considered to be the most effective method (19), but video/DVD and interactive computer training can also help.

Theoretical training without practice turned out to be futile. In the case of participants without previous skills in resuscitation, training children to perform CPR using audio-visual animation available on mobile phones has proven to be more effective than that assisted by a dispatcher, in terms of completing the check list and complying to the time interval spent for performing each CPR maneuver (20).

A training program creating virtual avatars who participated in team (multiplayer online simulation) to the CPR efforts was recently tested and is well appreciated by high school students thus trained (21).

Optimal method for assessing the effectiveness of CPR training

In one study using a game-based assessment of children skills in performing CPR (the student's outcome was equal to the number of cards collected by answering questions correctly as deemed by peers) the results were comparable to those obtained by the classical test method of paper-and-pencil (22).

Drawings are considered a familiar activity for children and one of their preferred means of communication; therefore, we can use this as an effective strategy for engaging them in CPR research (23). For example, in "You Can Also Save a Life!" Project, the pre- and post-training evaluations were performed by analyzing questionnaires and drawings (as non-verbal means of expression and communication) (3).

Several studies that analyzed the dilution of CPR information showed significant improvement in knowledge immediately after training, which suffered a regression towards baseline levels over time (24). Thus, the sequence submitted by us (training–evaluation of training quality–retraining at different stages of development: 2nd grade, 5th grade, 7th grade, 9th and 11th grade) is highly pragmatic.

CPR optimal instructors

Teachers seem to be most effective as instructors: they have adequate teacher training background and continuous contact with students; thus, training them to teach CPR represents a long term investment. It also raises the problem of the available training time, considering the school curriculum, the availability of training space and necessary equipment, as well as the need for a quality training of the trainers. CPR training caravans can be a solution as far as rural areas are concerned.

A questionnaire addressed to the primary, secondary or higher school teachers from Belgium comprising four distinct components (demographic, CPR knowledge and skills, attitudes towards their possible involvement in CPR training and personal experience CPR-related) found that only 59% of the respondents (2539/4273) were involved in doing CPR, mainly primary school teachers (69%) belonging to the age group 21-30 years (68%); compulsory training the CPR at school is backed by only 41% of the respondents, 61% stated that they do not feel able and do not want to teach CPR concepts especially due to insufficient knowledge and competence in CPR, 73% expressing willingness to undergo further training in this field (250). Training teaching staff of any level is particularly important: while in Romania there are 52,541 doctors (2011 data), the body of school teaching staff is larger: 37,391 teachers in pre-primary education, 120,927 teachers in primary and secondary education, 59,380 teachers in upper secondary education, 64 teachers in vocational training, 1,360 teachers in post-secondary education and apprenticeship, and 28,365 teachers in higher education (4).

The optimal instructor-trainees' ratio was variable in different studies: from 1:10 to 1:25 (26).

Optimal duration of CPR training

A study was recently conducted in two secondary schools in Germany over a period of four years (26). It included pupils of different ages (10-13 years), with 3 hours training duration (one hour of theoretical training and two hours of individual training on the manikin). The training frequency was annual or biannual and there were two types of instructors (teachers of the school, and emergency physicians). Children who started training at the age of 13 had better results in terms of theoretical knowledge, but there was no difference in practical skills to those whose training started at the age of 10, even if the instruction was repeated biannually or not, if it was done by the teachers of the school or by emergency physicians (26). Moreover, the courses have doubled the number of children who said that they were confident that the newly gained knowledge would enable them to save lives.

The use of automatic/ semi-automatic external defibrillators (AED)

The current data on Public Access Defibrillators (PAD), although disparate, indicates that the incidence of the cardiac arrest is reduced in schools as compared to other locations, so placing AEDs in schools is currently recommended only in three cases: if there is a reasonable probability of a cardiac arrest occurring there in the next five years; if there is at least one school pupil with increased risk of cardiac arrest; if the response time (the "call-to-shock" time) of the emergency medical system is longer than 5 minutes (27).

In the case of 6-7-year-old children, the score obtained after training in the use of

an AED has made investigators note that "use of an AED is just as simple for them as using a TV remote control" (28). Training children in the use of AED is obviously much simpler if such a device is kept in school. Even if it is not used frequently, the school can be considered as a possible location for placing an AED in the PAD program. The obstacles posed by the costs of such a defibrillator can be surmounted by means of the collaboration between the Health Ministry and the National Resuscitation Council.

National CPR training program in schools

An updated version of the national CPR training program should include a chapter dedicated to CPR training in schools. Within this segment of human education, it is possible to easily pass knowledge-skills-attitudes related to the "Good Samaritan" intervention onto children belonging to all social classes and to all ethnic groups (29). Starting CPR maneuvers as early as possible after the cardiac arrest can thus become possible as a result of the altruism and empathy of these young resuscitators. Training should be repeated every two years; the level of knowledge provided can be increased gradually; also gradually, emphasis can be put on motivational dialogues, the amendment of incorrect skills and on increasing efficiency to carry out optimal maneuvers. Training stages will be tailored to children's age and will include specific goals adapted to each stage (Table I), respecting the principle of revisiting CPR notions every two years. Training time will be adapted to each stage: 30 minutes of theory plus 60 minutes of practice in the first two stages and 60 minutes of theory plus 60 minutes of practice for the last three stages. Emotional education, particularly important, will be conducted in each of the five stages and will have an affective component related to the victim (altruism, empathy, social responsibility), as well as a component relating to the resuscitator himself/herself (motivation, increased confidence in the need for the correct sequence and full compliance with the appropriate CPR maneuvers, together with the increased confidence in one's own forces during CPR maneuvers) (30).

In stages 4 and 5 trainees can participate as volunteers assisting authorized instructors during the training of children in the initial stages on the basis of the principle of pyramidal distribution of the theoretical and practical information. All acquired knowledge spreads also to a secondary level represented by the trainee's parents and relatives, increasing the number of people who have access to the information. Training of trainers is essential for an efficient transmission "in oil stain" (i.e. horizontal) of this educational approach dedicated to CPR. Knowledge-skills-attitudes must be thoroughly checked in a system that will provide candidates for the role of trainee, trainer and overseer of the entire educational process.

Costs can be minimized without compromising in terms of equipment and quality, according to AHA (31) at the level of the cost of teacher education (2-4 teachers from each school: travel cost, course cost, substitute teachers to fulfill classroom responsibilities cost), the cost of the necessary equipment (manikins for BLS training in each school, supplies for training in BLS, training AED, supplies for use the training AED); we must add the costs of all the training materials (instructors toolkits, students manuals and CPR cards).

TABLE I

CPR training tailored to children's grade/age

Stage 1 3rd grade (age 9-10 years)	Stage 2 5th grade (age 12-13 years)	Stage 3 7th grade (age 13-14 years)	Stage 4 9th grade (age 13-14 years)	Stage 5 11th grade (age 17-18 years)
• Basic notions on blood circulation and cardiac arrest; • Recognition of cardiac arrest; • Knowing the unique European emergency phone number, i.e. 112; • Chest compressions – demonstration; • Understanding of AED - demonstration	• Basic notions on blood circulation and cardiac arrest; • Recognition of cardiac arrest; • Getting on the spot / by phone help - knowing the unique European emergency phone number, i.e. 112; • Communication with EMS dispatcher; • Ensuring airway patency - practice; • Chest compressions - practice • Operating an AED - practice	• Deeper understanding of blood circulation and cardiac arrest; • Recognition of cardiac arrest; • Identifying the premonitory signs of cardiac arrest; • Getting on the spot / by phone help - knowing the unique European emergency phone number, i.e. 112; • Communication with EMS dispatcher; • Ensuring airway patency - practice; • Chest compressions – practice; • Operating an AED – practice.	• Pre-course questionnaire; • Deeper understanding of blood circulation and cardiac arrest; • Recognition of cardiac arrest; • Identifying the premonitory signs of cardiac arrest; • Getting on the spot / by phone help - knowing the unique European emergency phone number, i.e. 112; • Communication with EMS dispatcher; • Ensuring airway patency – practice; • Ensuring breathing – practice; • Chest compressions – practice; • Operating an AED - practice	• Pre-course questionnaire; • Deeper understanding of blood circulation and cardiac arrest; • Recognition of cardiac arrest; • Identifying the premonitory signs of cardiac arrest; • Getting on the spot / by phone help - knowing the unique European emergency phone number, i.e. 112; • Communication with EMS dispatcher; • Ensuring airway patency – practice; • Ensuring breathing – practice; • Chest compressions – practice; • Operating an AED – practice; • Recovery position – practice.

AED Automated External Defibrillator; EMS Emergency Medical System.

Training children in schools has proven to be more cost-effective than in a training center setting. In order to convince schools to join the CPR training program, such a program should be promoted as a criterion for the accreditation or evaluation of primary schools, middle schools and high schools. In Romania, this program can be preliminarily implemented within the framework of the special education week

called *"Scoala altfel",* which is dedicated to extracurricular activities carried out in a non-formal context. This became an important component of the 'applied cardiology' strategy of the Romanian Society of Cardiology (32).

The role of the Minister of Education and Scientific Research is particularly important in this field. The "European Cardiac Arrest Awareness Day" (16 October, each year), set up by the European Parliament and adopted by the European Resuscitation Council and Romanian National Resuscitation Council already had three editions and the main element of both was the CPR education of children.

CONCLUSIONS

The knowledge and implementation of CPR maneuvers constitute a social binder (an individual can be saved by any other individual) contributing to the culture of cohesion and to the respect of life itself. Upon graduation, each student is supposed to own a range of useful knowledge about day-to-day life. The basics of CPR are a vital part of this knowledge and should be valued accordingly.

TREATMENT OF METABOLIC ALTERATIONS IN POLYCYSTIC OVARY SYNDROME (Abstract). Polycystic ovary syndrome is a common endocrinopathy characterized by oligo ovulation or anovulation, signs of androgen excess and multiple small ovarian cysts. It includes various metabolic abnormalities: insulin resistance, hyperinsulinemia, impaired glucose tolerance, visceral obesity, inflammation and endothelial dysfunction, hypertension and dyslipidemia. All these metabolic abnormalities have long-term implications. Treatment should be individualized and must not address a single sign or symptom. Studies are still needed to determine the benefits and the associated risks of the medication now available to practitioners. **Keywords**: POLYCYSTIC OVARY SYNDROME, METABOLIC SYNDROME, COMBINED ORAL CONTRACEPTIVES.

Polycystic ovary syndrome (PCOS), a frequent endocrine dysfunction among women of reproductive age, has important short- and long-term metabolic consequences thus affecting the quality of life. According to the Rotterdam consensus, PCOS is defined by two of the following three criteria: irregular or absent ovulation, androgen excess (clinical or laboratory findings, following the exclusion of other pathologies, such as androgen-secreting tumors, Cushing's syndrome etc) and enlarged ovaries with at least 12 antral follicles each (1). This syndrome is characterized by various metabolic abnormalities: insulin resistance (IR), hyperinsulinemia, impaired glucose tolerance (IGT), visceral obesity, inflammation and endothelial dysfunction, hypertension and dyslipidemia. The management of these imbalances and their impact on health is still a challenge.

Etiology. The etiology remains unclear, but it involves interactions between endocrine (hypothalamic, ovarian, adrenal), genetic, environmental and behavioral factors (2). The sequence of the phenomena is unclear: it has not been established whether hyperandrogenism results from hyperinsulinemia secondary to insulin resistance (IR) or vice versa, but increasingly more studies show that hyperinsulinemia plays an important role in the pathogenesis of this syndrome.

Physiopathogenesis. Women with PCOS have certain metabolic and cardiovascular abnormalities. Obesity is common

among them and is associated with increased IR, IGT and dyslipidemia. IR is present in 60-80% of women with PCOS, and is more prevalent among the obese ones. Obesity seems to be the main factor for the development of IR, but defects in post-receptor intracellular signaling also seem to play a role. IR and the resulting hyperinsulinemia are found in both normal weight and overweight or obese women and significantly increase the prevalence of IGT and diabetes mellitus type 2 (DM2) in women with PCOS. Up to 35-40% of women with PCOS have IGT and 10% will develop DM2 in the third and fourth decade of life. IGT and DM2 are common among women with PCOS, and significant percentage of teenage women (mainly obese) are at risk of developing these diseases.

Dyslipidemia is another metabolic abnormality in women with PCOS and includes: increased levels of total cholesterol, LDL-C and triglycerides (TG) and low levels of HDL-C. Genetic and ethnic factors, hyperandrogenemia and obesity are linked to dyslipidemia in women with PCOS.

In women with PCOS, especially in the presence of obesity, elevated levels of the markers of cardiovascular disease have been reported (C-reactive protein (CRP), endothelin-1, adiponectin, homocysteine, plasminogen activator inhibitor-1 (PAI-1), von Willebrand factor and markers of oxidative stress.

There is a substantial overlap between PCOS and the metabolic syndrome (MS), a group of metabolic disorders related to increased cardiovascular risk (3). The International Diabetes Federation consensus (2006) definition of MS is central obesity (waist circumference) and 2 of the following criteria: raised triglycerides: over 150 mg/dL (1.7 mmol/L), low HDL-C: below 40 mg/dL (1.03 mmol/L) in men and below 50 mg/dL (1.29 mmol/L) in women, raised systolic blood pressure > 130 mmHg or diastolic blood pressure > 85 mmHg, raised fasting blood glucose or DM2. The prevalence of MS in PCOS varies between 1.6% and 43% depending on the population studied (4, 5). In PCOS, the most common features are decreased HDL-C, obesity and high blood pressure (4). In the general population, MS leads to a 2-fold increase in cardiovascular risk. In women with PCOS there is limited evidence of cardiovascular events of increased heart disease mortality.

Given the multifactorial pathogenesis of PCOS, a multidirectional therapeutic strategy should be established. Currently there are many drugs that can be used, but which, although may be beneficial for certain metabolic aberrations, can aggravate other abnormalities. Some treatment options include: oral contraceptives and antiandrogens, oral antidiabetic agents (metformin, thiazolidinedione), statins, acupuncture, various dietary supplements (vitamin D, vitamin B1, folic acid) or hygienic-dietary regimes.

TREATMENT

1. CONTRACEPTIVES. Oral contraceptives have been the treatment of choice of PCOS for many years, especially combined oral contraceptives (COCs), but progestin only minipills have also been used. COCs contain an estrogen component (ethynyl-estradiol or estradiol) and a progesterone, which varies according to the type of pill. In most PCOS women, oral contraceptives resulted in amelioration of clinical manifestations, such as normalization of menstrual cycles, hirsutism and acne relief, and sometimes to regression of

male pattern alopecia. The effects are assigned to the decreased LH secretion, inhibition of ovarian and adrenal androgen production, and reduced free testosterone levels due to increased liver production of SHBG.

Contraceptives are not used specifically for the treatment of metabolic alterations, even though they inflict various influences on the metabolism. On the contrary, some studies suggest that oral contraception may have a negative effect on metabolic abnormalities in PCOS women.

There is an association between their use and development of IR, which suggested a potential adverse effect on the metabolism, but the results of the studies are yet inconclusive. Their influence on carbohydrate metabolism varies from DM to its improvement. Studies show that low-dose estrogen COCs (<50mcg) are associated with decreased risk for DM2, but investigations are still needed in order to determine the progestogen with the lowest impact on carbohydrate metabolism. Studies on the impact of COCs on lipid metabolism have limitations due to their heterogeneity, leading to inconsistent results. In general, it has been shown that treatment with oral contraceptives leads to an increase in LDL-C, total cholesterol, HDL-C and TG (6). Minipill administration seems not to interfere with lipid parameters (7). Increased TG seems to be the most common side effect of contraceptive treatment (6,7). The potential effect of this type of treatment appears to be the result of the action of estrogen on liver, by lowering TG clearance, so COCs with lower estrogen doses may lead to a lower increase of TG levels and transdermal systems might not affect the lipid profile (8). In addition, various COCs lead to increased HDH-C levels, the effect being attributable to the action of estrogen component on the apolipoprotein AI gene expression in liver cells. A Cochrane review (9) analyzed the results of four randomized trials comparing oral contraceptives with metformin and showed no differences between the 2 types of treatment in clinical metabolic effects (development of DM2 and cardiovascular diseases) and biological effects (insulin, glucose, total cholesterol), the only difference being the increase of TG in contraceptive therapy as compared to the metformin therapy.

Regarding hypertension, COCs can induce high blood pressure and are therefore contraindicated in hypertensive women with PCOS and should be stopped if hypertension develops during treatment.

The effect of oral contraceptives on weight is still controversial: some studies found an increase in body weight while others showed no differences in weight (10).

In conclusion, oral contraception may have a negative effect on metabolic abnormalities in PCOS women and the long term benefits are unclear, especially in patients with IGT, DM2 and dyslipidemia. The decision to administer this treatment must take into account the patient's phenotype and history.

2. ANTIANDROGENS. In women with PCOS, hyperandrogenemia was suggested as an initiating factor of metabolic abnormalities. Androgens exert their effects through the androgen receptor, which is expressed in the visceral adipose tissue, acting through competitive inhibition and by decreasing androgen production. In addition, the direct effect on insulin signaling pathway appears to contribute directly to IR in PCOS. Antiandrogens, such as cyproterone acetate, spironolactone and

flutamide, have been used in women with PCOS mainly for the treatment of hirsutism. They are generally used in combination with oral contraceptives, having synergistic effect, but also because a contraceptive method during the treatment with antiandogens is required because of the potential feminization of male fetuses.

Cyproterone acetate is a progestational antiandrogen which competitively inhibits the binding of testosterone and its more potent conversion product 5*a*-dihydrotestosterone to the androgen receptor.

Spironolactone is an aldosterone antagonist and a competitive inhibitor of the androgen receptors. Its use leads to the inhibition of androgen production and of the action of 5α reductase. In normal weight women it increases HDL-C and lowers TG (11).

Flutamide is a selective androgen receptor with progesterone-like activity. It reduces the conversion of testosterone to its more active metabolite, dihydrotestosterone, in the target tissues. In patients with PCOS it improves the androgenic manifestations. The effect on carbohydrate metabolism is insignificant, but it lowers total cholesterol, LDL-C and TG, independent of body mass. Used in conjunction with COC and metformin it causes a sharp decrease in LDL-C and increase in HDL-C, but does not prevent TG increase associated to COCs (12).

3. ORAL ANTIDIABETICS. The strong association between IR and PCOS led to the use of drugs that increase the sensitivity to insulin ("insulin sensitizers") in the treatment of this syndrome.

Metformin, a biguanide, acts mainly by suppression of hepatic gluconeogenesis, but also increases peripheral insulin action in skeletal muscle and decreases glucose uptake from the digestive tract, without having a direct effect on pancreatic insulin production. It improves the lipid profile through various mechanisms and directly inhibits thecal cell androgen production.

In women with PCOS, metformin appears to improve the cardio metabolic parameters by increasing insulin sensitivity, lowering blood glucose and androgenemia, but these effects are more obvious if there are associated with lifestyle changes. Metformin may normalize appetite in obese women with PCOS through normalization of neuropeptide Y, which is low in women with PCOS.

Some studies have shown that patients with PCOS and hyperinsulinemia treated with metformin benefited from a significant decrease in total cholesterol, LDL-C and TG and increased HDL-C, but these benefits have not been demonstrated in patients with severe obesity. Metformin appears to improve some atherogenic factors: endothelin-1, adhesion molecules, CRP, advanced glycation products (AGE).

Other drugs that increase insulin sensitivity are thiazolidinedione (glitazones), which act by binding to and activating the PPAR-gamma receptor (peroxisome proliferator-activated receptor gamma). Pioglitazone is the only one that can be used in Europe today. There is insufficient evidence of the metabolic benefits in women with PCOS, although pioglitazone monotherapy in obese women with PCOS improves the lipid profile (13) and decreases the serum PAI-1 and CRP levels.

4. OTHER THERAPEUTIC METHODS. Statins act by the selective inhibition of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, which is involved in the biosynthesis of cholesterol. In

women with PCOS, statins have different effects, other than reducing lipids (especially LDL-C): they reduce the thecal production of androgens and steroidogenesis (14) and the effects of RI and associated hyperinsulinemia, have antioxidant and anti-proliferative effects, and appear to improve the cardiovascular morbidity and mortality associated with PCOS. However, they are teratogenic and cannot be used in women with PCOS who are planning a pregnancy.

As to the use of acupuncture in women with PCOS, although clinical trials are lacking, animal studies show that electro acupuncture could improve the cardio metabolic abnormalities in PCOS: it activates muscle fibers (which increase blood flow, peripheral insulin sensitivity and peripheral glucose utilization), stimulates the release of neuropeptides in the central nervous system (β-endorphins) and could reduce sympathetic activity, which results in lower levels of circulating testosterone (15).

In women with PCOS, low levels of vitamin D are associated with IR, obesity, IGT and MS, suggesting a possible role of this vitamin in the pathogenesis of PCOS (16). Administration of vitamin D in PCOS improves the lipid profile and IR, but further studies are needed.

It has been shown that the administration of vitamin B12 in patients with MS decreases IR. In women with PCOS, IR, obesity and elevated serum homocysteine levels are associated with low serum concentrations of vitamin B12 (17), suggesting a possible role of this vitamin in the treatment of PCOS.

CONCLUSIONS

Polycystic ovary syndrome is characterized by multiple metabolic abnormalities and has significant long-term implications. The therapeutic strategy encompasses numerous approaches and drugs, as the physiopathogenesis of the syndrome is being better understood.

In our opinion, the treatment should be individualized, must not address a single sign or symptom and should also take into account the possible side effects. We believe that further studies are still needed to determine the benefits and risks of medicines that are now available to the practitioners, as well as the long-term cardiovascular implications. Given the complexity of the syndrome, we advocate a multidisciplinary treatment approach (gynecologist, endocrinologist, cardiologist, nutritionist).

NEWS

CLINICAL AND MICROBIOLOGICAL EVALUATION OF SCALING AND ROOT PLANING PER QUADRANT AND ONE-STAGE FULL MOUTH DISINFECTION ASSOCIATED WITH AZITHROMYCIN OR CHLORHEXIDINE

Conflicting data about the protocol of choice for non-surgical periodontal therapy with adjuvant use are still reported. The study realized by a group of brazilian researchers aimed to evaluate, through clinical and microbiological parameters, the systemic use of azithromycin as adjuvant to non-surgical periodontal treatment performed by one-stage full-mouth disinfection within 24 hours or conventional quadrant scaling in four weekly sections. In the randomized controlled trial, 85 patients diagnosed with chronic periodontitis underwent different treatment protocols, divided in 6 groups: 3 full-mouth disinfection groups (with no adjuvants, with chlorhexidine and with azithromycin) and 3 weekly sections groups (with no adjuvants, with chlorhexidine and with azithromycin). Clinical periodontal parameters, total and quantitative bacterial counts of Aggregatibacter actinomycetemcomitans, Porphyromonas gingivalis, Tannerella forsythia, Treponema denticola, and Streptococcus oralis were measured through real-time polymerase chain reaction at baseline, 90, and 180 days after treatment. In all groups, it was observed a significant reduction in the % of periodontal diseased sites, gingival index, plaque index, and clinical attachment level gain at 90 days of treatment, demonstrating effectiveness of the treatment, independently of the adjuvant. The full-mouth disinfection with chlorhexidine group showed higher reduction in probing depth and % periodontal diseased sites, as well as lower total bacterial count than all the other groups at 180 days. In conclusion, the adjuvant use of azithromycin did not provide any significant benefit, independently of the treatment protocol. The adjuvant use of the chlorhexidine showed a more expressive and significant improvement on clinical and microbiological parameters, especially in the full-mouth disinfection protocol, followed by weekly sections (Campideli Fonseca D, Cortelli JR, Cortelli SC, Miranda Cota LO, Machado Costa LC, Moreira Castro MV, Oliveira Azevedo AM, Costa FO. Clinical and Microbiological Evaluation of Scaling and Root Planing per Quadrant and One-Stage Full Mouth Disinfection Associated With Azithromycin or Chlorhexidine: A Clinical Randomized Controlled Trial. *J Periodontol.* 2015 ; 7: 1-16).

ASSESSMENT OF ADVERSE DRUG REACTIONS AS CARDIOVASCULAR RISK FACTORS (Abstract): A wide range of pharmaceutical substances can induce side-effects expressed as cardiovascular changes or events, adding to other risk factors or worsening preexisting cardiovascular diseases. **Aim:** Continuous study focused on iatrogenic conditions representing cardiovascular risk factors. **Methods:** We developed a descriptive study of patients admitted to the Iasi Vth Internal Medicine and Geriatrics-Gerontology Clinic between 1998-2013, focusing on iatrogenic conditions representing cardiovascular risk factors. **Results:** We have diagnosed 81 cases of drug-induced hypertension, and 43 patients with hypertensive crises; 72 cases of iatrogenic hyperglycemia; 36 cases of drug-induced hyperuricemia; 50 cases of drug-induced dyslipidemias; and 17 cases of iatrogenic obesity. These iatrogenic diseases were more common in women and the elderly. Twenty-eight patients have developed simultaneous adverse drug reactions induced by the same drug and manifest as different cardiovascular risk factors. **Conclusions:** Cardiovascular risk factors can be induced to a significant extent by chronic drug administration. Some medications (e.g. NSAIDs, corticoids, β-blockers, diuretics, contraceptives) can act on the same patient by multiple pathogenic links. The adverse drug reactions can be cardiovascular risk factors that persist in time, or can be removed (by discontinuing the administration of the implicated drug). The highest importance of their acknowledgment relies on the possibility of their prevention through carefully balancing the benefits and the risk of each new medication. **Keywords:** DRUG-INDUCED SIDE-EFFECTS, CARDIOVASCULAR DISEASES, CARDIOVASCULAR RISK FACTORS, IATROGENESIS.

World Health Organization defines pharmacovigilance as "the science and activities relating to the detection, assessment, understanding and prevention of adverse effects or any other drug-related problem". The importance of pharmacovigilance lies in its key place in the public health care system (1).

A wide range of pharmaceutical substances can induce side-effects expressed as cardiovascular events, adding to other risk factors or worsening preexisting cardiovascular diseases. In countries with a very rigorous pharmacovigilance activity, such

as the Netherlands and UK, these cardiovascular iatrogenic effects reach up to 10% of all annual reported iatrogeneses (2). The most frequently found are heart rhythm disturbances, heart failure, high blood pressure, myocardial ischemia, thromboembolic disease, myocardial toxicity, valvular and pericardial heart disease (3,4,5).

Life-threatening adverse drug reactions (ADR) reports were submitted by patients in a range of 8.6% in Denmark up to 13% in Netherlands (2,6,7).

MATERIAL AND METHODS

We developed a continuous study aimed at identifying iatrogenic conditions representing cardiovascular risk factors in a population of hospitalized patients. Thus, we searched for iatrogenic hypertension, diabetes, dyslipidemia, obesity and hyperuricemia that might have occurred before admission or during hospital stay.

The observational study recorded the adverse reactions occurring in patients admitted between 1998-2013 to the Iasi Vth Internal Medicine and Geriatrics-Gerontology Clinic of the "Railway Hospital". The studied population consisted of 18,740 patients, of which 8,900 (47.49%) women and 9,840 (52.51%) men.

In order to establish the possibility of a drug side-effect the classical criteria of incrimination used in pharmacovigilance were used (8). Besides this intensive surveillance, some other clinical trials were designed in order to determine if the first assumptions are supported.

The study continued with a follow up of these patients during current and second admission for either an acute event or reassessment of their health status. One hundred ninety-nine patients only benefited from outpatient consultation.

RESULTS

1496 (7.98%) of the patients presented 1677 different types of adverse drug reactions (some of the patients experiencing more side effects) with different degrees of severity. Out of them 243 patients (16.24%) presented 299 adverse drug reactions that can be considered cardiovascular risk factors: hypertension, diabetes, dyslipidemia, obesity and hyperuricemia.

Age and sex distribution of the 299 cases with adverse reactions is shown in fig. 1 (some patients manifested multiple side effects) (fig. 1) and they were statistically analyzed (Data_cases of pharmacovigilance.xls).

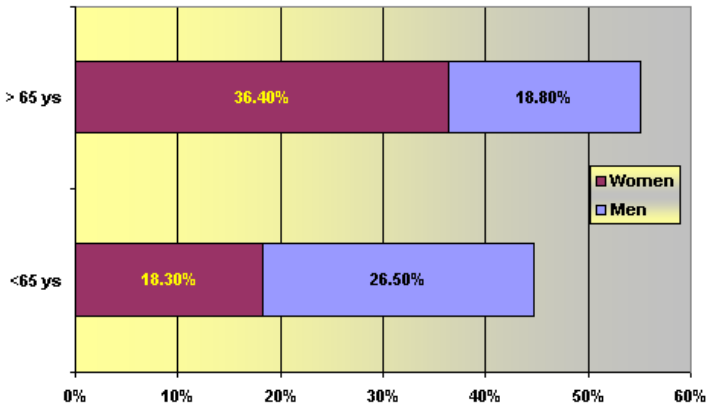

Fig. 1. The age and sex distribution of adverse drug reactions

The recorded iatrogenic effects were found in patients with cardiovascular diseases on long-term or short-term medication administered to treat different conditions or to reduce multiple risk factors (tab. I).

TABLE I

Adverse drug effects caused by the incriminated drugs

Adverse drug reaction	Incriminated drug	No of cases
Hypertension	Nonsteroidal anti-inflammatory drugs (NSAIDs)	25
	Oral contraceptives	17
	Corticosteroids	14
	Monoamine oxidase inhibitors (MAOIs)	7
	β-mimetics	5
	Thyroid hormones	5
	Anabolic steroids	5
	α-interferon	3
Hypertensive crises	Beta-blocker withdrawal syndrome	12
	NSAIDs	20
	Thyroid hormones	11
Diabetes mellitus/ impaired fasting glucose and/or impaired glucose tolerance	Diuretics (thiazide, furosemide, indapamide)	26
	Oral contraceptives	12
	Oral corticosteroids	9
	NSAIDs	5
	Atypical antipsychotic medications (olanzapine)	5
	β-blockers	4
	Calcium antagonists	3
	Nalidixic acid	3
	Intra-articular administration of corticosteroids	2
	Ciprofloxacin	2
	Propafenone	1
	Statin	1
Hyperuricemia	Diuretics (thiazide, indapamide)	25
	Salycilates	7
	Phenylbutazone	3
	Ranitidine	1
Dyslipidemias	Diuretics (thiazide)	17
	Oral contraceptives	11
	Corticosteroids	8
	Atypical antipsychotic medications (olanzapine)	8
	β-blockers	5
	Angiotensin -converting enzyme inhibitors	1
Obesity	Cortisone	6
	Atypical antipsychotic medications (olanzapine)	6
	Anabolic steroids	4
	Statin	1

Drug-induced hypertension was found as an adverse drug reaction in 81 cases (33.33%), more frequently involved being the nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives and corticosteroids. Monoamine oxidase inhibitors (MAOIs), β-mimetics, thyroid hormones, anabolic steroids or α-interferon were also incriminated in drug-induced hypertension, but with a lower frequency.

In agreement with other authors (9,10), we found neither specific clinical criteria for drug-induced hypertension (patients presenting with a wide range of clinical manifestations) nor temporal criteria (the onset as well as the time to the normalization of blood pressure in case of withdrawal being highly variable). In most of the cases with hypertension caused by NSAIDs and oral contraceptives (which were the leading cause), patients had taken the medication without medical prescription, and did not follow the instructions (low sodium diet).

The rise in blood pressure was usually mild, but 11 cases (4.53%) developed severe hypertension and discontinuing the incriminated drug led to the normalization of blood pressure within 2 weeks - 6 months.

The triggering of hypertensive crisis in 43 patients (17.70%) already known with high blood pressure was recorded in 3 situations: withdrawal syndrome following cessation of antihypertensive drug therapy (the abrupt discontinuation of β-blocker treatment) in 12 cases (4.94%), higher blood pressure levels associated with NSAIDs administration confirmed by 24-hours arterial blood pressure measurements in 20 patients ((8.23%), and hypertensive episodes in 11 patients (4.53%) on thyroid hormone replacement therapy.

Diabetes mellitus was the second most frequent cardiovascular adverse effect.

A correlation between the administration of a drug and the occurrence of hyperglycaemia was found in 72 patients (29.63%). In 58 cases (23.87%), the incrimination of the drug was very likely. The drugs most frequently involved were diuretics (thiazide, frusemide, indapamide), oral contraceptives and oral corticosteroids, followed by NSAIDs and atypical antipsychotic medications (olanzapine). Some patients had a history of chronic treatment for such diseases as tuberculosis (isoniazid and rifampicin), or persistent lumbar pain (NSAIDs). In a small number of patients we have noticed the involvement of amiodarone, statin, and atypical antipsychotic medication (olanzapine) in the onset of diabetes mellitus.

The relationship between drug use and hyperglycemia was weaker (possible or likely reaction) in 10 cases, and was related to β-blockers, calcium antagonists and nalidixic acid. Intra-articular corticosteroids, ciprofloxacin and propafenone produced this side effect with a lower frequency.

Of the drugs with hyperglycemic effect, only those well-known to induce this metabolic effect were most likely incriminated, but of the drugs with a smaller coefficient of incrimination (< 5), some less mentioned drugs like ciprofloxacin, or never mentioned – as propafenone – were responsible for this side-effect.

Hyperglycemic crisis, possibly secondary to drugs was found in 2 patients (0.82%) that were long-term treated with nifedipine and 1 patient receiving verapamil on long-term; if this side-effect of nifedipine is already known, the role of verapamil is controversial, some authors advocating

its hyperglycemic role or pleading for its hypoglycemic role, while others support its neutral role on the carbohydrate metabolism (11,12).

Drug-induced hyperuricemia (or iatrogenic hyperuricemia) (13) was found in 36 cases (14.81%) and was mainly caused by chronic diuretic use, as mentioned above, in 25 cases (10.29%). In other 7 cases (2.88%), secondary hyperuricemia was due to salycilates, while the frequency of this side-effect in patients treated with ranitidine and phenylbutazone was lower.

Diuretic-induced gout occurred in 11 cases (4.53%), and it was reversible following withdrawal of the drugs in 10 cases, while in 1 case it required treatment with allopurinol.

Drug-induced dyslipidemia (14) was diagnosed in 50 patients (20.58%). In the majority of cases, diuretics and oral contraceptives, together with corticosteroids and olanzapine caused different types of secondary iatrogenic dyslipidemias.

Obesity was recorded in 17 cases (~7%) on long-term medication use. Most drug-induced weight gain effects were the result of chronic treatment with cortisone and olanzapine. In few patients obesity was associated with an adverse drug reaction to anabolic steroids or statin regimen.

Our study proves that atypical antipsychotic medication increases the likelihood of many cardiovascular risk factors, confirming the conclusion that weight gain and metabolic disease in patients taking second-generation antipsychotic medications "represents an epidemic within an epidemic" (15).

The discontinuation of suspected drugs led to normalization of clinical and biological data in less than 3 months in the acute forms and in less than 6 months in the chronic ones. 17 patients (~7%) were lost tofollow up. No rechallenge was voluntarily administered.

DISCUSSION

Patients developing drug-induced diabetes mellitus or hyperglycemia were not previously known with diabetes mellitus or with abnormal glucose tolerance, although, theoretically, diabetics are more prone to develop this side-effect. On the other hand, the acknowledgement of the hyperglycemic effect of some drugs makes doctors to avoid their usage in diabetics.

We have found no causal relationship between the corticosteroid dose and the occurrence of hyperglycemia in non-diabetic patients; conversely, an increased likelihood of corticosteroids dose-related hyperglycemia was found in diabetics.

All patients with oral or intra-articular administration of corticosteroids were diabetics, and hyperglycemia occurred when, for various reasons, the patient has been given a higher dose than the initial one.

Statin-induced hyperglycemia was described in a 72-year-old woman, who also exhibited muscle weakness upon standing and walking, particularly in the quadriceps muscles, within 15 days of treatment for hypercholesterolemia. After statin administration was discontinued, blood sugar level returned to normal within 5 days, but, nevertheless, the patient was still complaining of muscle soreness and decreased exercise tolerance for another month. The cardiovascular risk might be augmented by the imposed sedentary behaviour. Symptoms had a lower intensity after one month, when she went to the ambulatory care clinic, and the caregiving team reassured and encouraged her to practice daily limb exercise training and walking.

A higher frequency of iatrogenic diseases was found in women, which general-

ly consume more frequently over-the-counter medication such as NSAIDs, diuretics, contraceptives. The long-term medication that led to the occurrence of adverse drug reactions was self-medication in 49 cases (20.16%), out of which almost 71% (35 cases) were women.

The higher frequency of iatrogenic disease in the elderly is caused by age-related alterations in pharmacokinetics and pharmacodynamics, polypragmasia (due to polypathology at this age), predisposition to many unwanted interactions and difficult cooperation with the old patient (16,17).

The importance of drugs as cardiovascular risk factors relies not only in their frequency (lower than other etiologies), but especially in the fact that they represent modifiable risk factors (therefore they are avoidable by ceasing treatment, if the administration is not absolutely necessary). It is also important to acknowledge the possibility that the same drug may simultaneously induce multiple risk factors (e.g.: corticosteroids, NSAIDs, β-blockers, diuretics, contraceptives) (18). The adverse drug reactions proved to be cardiovascular risk factors that disappeared within several days to several weeks after withdrawal of suspected drug and persisted for months only in three cases of obesity.

The more frequent occurrence of these iatrogenic effects in older women, as proved by this study, requires an increased focus on this segment of the population (considering that they additionally lose cardiovascular protection due to the drop in estrogen level associated with menopause).

Our study describes the following paradox: trying to treat cardiovascular risk factors may cause other cardiovascular risk factors. Moreover, a patient receiving multiple medication in order to avoid the occurrence of cardiovascular disease may become incompliant, ignoring the effects of diet and physical exercise. It is the physician's role to inform the patient on the possible negative effects of polypragmasia and the beneficial role of a healthy lifestyle (19,20).

CONCLUSIONS

1. The study proved that cardiovascular risk factors can be induced to a significant extent by chronic drug administration.

2. Some drugs (NSAIDs, β-blockers, diuretics, contraceptives) cause simultaneous cardiovascular adverse reactions in the same patient by multiple pathogenic links.

3. The adverse drug reactions disappeared within several days to several weeks after the discontinuation of the suspected drug and rarely persisted for months.

4. The highest importance of their acknowledgment relies on the possibility of their prevention through carefully balancing the benefits and risk of each new medication.

5. The adverse reactions can be counteracted by healthy lifestyle interventions, comprising balanced diet and regular exercise training, habits that can be enhanced through counselling and continuous medical education.

EVALUATION OF PROGNOSTIC FACTORS IN DECOMPENSATED LIVER CIRRHOSIS WITH ASCITES AND SPONTANEOUS BACTERIAL PERITONITIS **(Abstract)** Mortality in spontaneous bacterial peritonitis (SBP) decreased significantly from 90% in 1970 to 10-30% today, but SBP still remains a complication with a poor prognosis. Although there are new preventive measures, such as early diagnosis and treatment with albumin, the introduction of new antibiotics, the prognosis of patients with decompensated cirrhosis and SBP remains poor, with a mortality rate of 20-40%. The installation of an episode of spontaneous bacterial peritonitis reduces the survival rate at 1 year to 30% and to 20% at 2 years. **Purpose**: In this context, the identification of patients with increased risk of death is extremely important in order to improve prognosis. **Material and Methods**: The prospective study included 153 patients with cirrhosis admitted to the Institute of Gastroenterology and Hepatology Iaşi from 1 January to 31 December 2010, reevaluated during 2 years. Criteria for the diagnosis of SBP were the presence of a number> 250 PMN / mmc. The presence of ascites and / or upper gastrointestinal bleeding (UGB) marks the decompensated cirrhosis. To assess the severity of cirrhosis, there were used Child-Pugh and MELD scores. Diagnostic paracentesis and ascites fluid cultures were performed in all hospitalized patients with ascites and also in case of signs and symptoms of SBP, before and after antibiotic treatment. Lack of response to empirical therapy was considered in those cases with a decrease in the number of neutrophils <25% from baseline. **Results**: Identification of patients with increased risk of death is extremely important to improve prognosis. In peripheral leukocytosis and in the ascites fluid, low hemoglobin can be considered predictors of mortality in patients with PBS. Child-Pugh score, increased levels of bilirubin and creatinine and hyponatremia are independent risk factors of mortality in patients with SBP. Bacteremia and lack of therapeutic response are independent risk factors of mortality associated with SBP. Recent history of variceal bleeding, severity of infection and the degree of hepatic and renal impairment influence short-term prognosis of patients with SBP. **Conclusions**: Identification of patients with increased risk of death is extremely important to improve prognosis. Therefore, it is important to identify prognostic factors in patients with bacterial infection and cirrhosis, in order to identify high risk patients and to prevent complications and death. **Keywords**: SPONTANEOUS BACTERIAL PERITONITIS, RISK FACTORS, TREATMENT, PROGNOSIS.

Spontaneous bacterial peritonitis occurs in 24% of cirrhotic patients with ascites (1). Although preventive measures are taken, such as early diagnosis and treat-

ment with albumin, the introduction of new antibiotics, the prognosis of these patients remains poor, with a mortality rate of 20-40% (2, 3, 4). The installation of an episode of spontaneous bacterial peritonitis reduces the survival rate at 1 year to 30% and to 20% at 2 years. Almost one third of patients diagnosed with liver cirrhosis complicated with spontaneous bacterial peritonitis (SBP) develop hepato-renal syndrome, with a high mortality rate. Another complication that occurs in SBP is hepatic encephalopathy, ascites becomes refractory to treatment and recover rapidly after paracentesis (5, 6).

The appearance of multi-resistant (MR) bacteria has a major impact on the clinical course of patients with cirrhosis. In a prospective study on this topic, the response to empiric treatment in community-acquired infections was high (83%) but decreased in healthcare-associated infections (73%) and extremely low in nosocomial infections (40%) (7).

Bacterial infection is a leading cause of circulatory dysfunction. Infection in cirrhosis is associated with an inflammatory response more important than in non-cirrhotic population. Therefore, cirrhotic patients with SBP show very high levels of cytokines, which emphasizes the circulatory dysfunction (2). The infection in a patient with basic circulatory dysfunction can be devastating. Up to 30% of patients develop progressive circulatory dysfunction and acute renal failure, heart failure, hepatic encephalopathy and hepatorenal syndrome type-1 and death. Albumin increases the effective arterial volume, reduces renal failure and improves survival in SBP (8, 9).

MELD (Model for End-Stage Liver Disease) score predicts survival at three months in cirrhotic patients and in those enrolled in liver transplantation. As it proved to be insufficient, a new score iMELD was defined, with higher accuracy in predicting mortality. Besides bilirubin and creatinine levels, there were included age and serum sodium (Na lower 130mmol / l). This score shows that hyponatremia is an independent risk factor predicting mortality in cirrhotic patients with SBP (10). SBP mortality decreased substantially from 90% in 1970 to 10-30% today, but it still remains a complication with poor prognosis.

The purpose of the study is to evaluate patients with liver cirrhosis and SBP, assessing the survival rate of patients with ascites and SBP, and analyzing clinical, biological, echographic and endoscopic characteristics associated with worsening of the prognosis.

MATERIAL AND METHODS

The prospective study included patients with liver cirrhosis of different etiologies, hospitalized in the Institute of Gastroenterology and Hepatology Iasi in the period 1 January 2010 to 31 December 2010, which were clinically and laboratory investigated at the time of presentation and evaluated annually for 2 years. Socio-demographic data, personal history and symptoms were assessed and recorded in all patients. Complete clinical examination and history were achieved in all cases. The diagnosis of cirrhosis was established corroborating data obtained by objective clinical examination and laboratory investigations (hematology, biochemistry, abdominal ultrasound, upper gastrointestinal endoscopy).

A SBP essential diagnostic criterion was the presence of a number a PMN more than 250 PMN / mmc. Compensated cirrhosis was defined as cirrhosis without ascites. Ascites and / or variceal bleeding is a sign

of decompensated cirrhosis.

Child-Pugh score and MELD score were used to assess the severity of liver cirrhosis. Diagnose paracentesis and ascites fluid culture was performed in hospitalized patients at their admission and in case of signs and symptoms of SBP also during hospitalization period. Ascites fluid was investigated macroscopically, biochemically (albumin, protein), cytologically (cellular) and bacteriologically (smear and culture). Lack of response to empirical treatment was noticed in cases of general condition alteration and decrease PMN <25% of baseline.

Written informed consent for study participation was obtained after informing.

The processing of statistical data was performed with STATISTICA software var. 7.0, evaluating the annual rate of decompensation and analyzing the risk factors of decompensation with ascites and SBP.

RESULTS

The initial group in the study included 153 patients, 30.72% diagnosed with compensated cirrhosis and 69.28% in decompensated stage. At the end of the study, 9.87% of patients remained in the compensated stage of disease, and 91.45% were in decompensated stage. At the end of the study there were 14 deaths (tab. I).

The main causes of death were: spontaneous bacterial peritonitis (64.29%), hepato-renal syndrome (57.14%) and variceal bleeding (35.72%) (fig. 1).

TABLE I

Frequency of cases with compensated and decompensated cirrhosis

Patients	Stage I		Stage II		Stage III	
	n	%	N	%	N	%
Group with cirrhosis	153	100	153	100	152	99,35
Group with compensated cirrhosis	47	30,72	23	15,03	15	9,87
Group with decompensated cirrhosis	106	69,28	130	84,97	139	91,45
Deaths	0	0	1	0,65	13	8,55

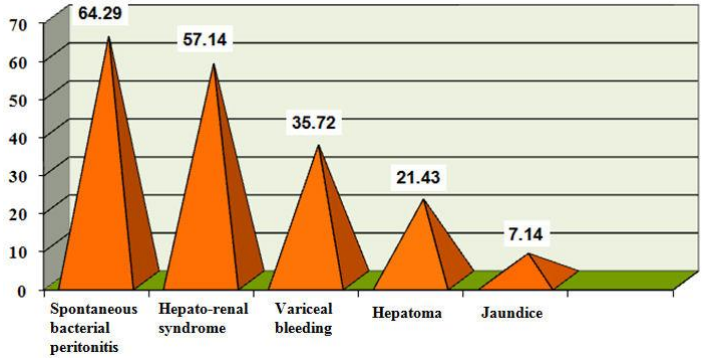

Fig. 1. Frequency of causes of death

To highlight potential risk factors and death associated with SBP, we compared different nonparametric variables in the subgroup of patients with SBP or the subgroup of patients who later died with similar values corresponding to the rest of the

group (patients without SBP), and we identified the possible risk factors of SBP and death.

The significant results were presented in the following tables and graphics.

In the patients who subsequently died, there were significantly higher mean values of blood leukocytes in both the onset phase of the study and also in the examinations at 1 and 2 years (fig.2). Mean values of leukocytes in ascites fluid at 1 and 2 years, and also the average values of PMN in ascites fluid at 1 and 2 years were higher (fig. 3).

Mean values of creatinine in surviving patients were lower compared to the dead ones (fig. 4).

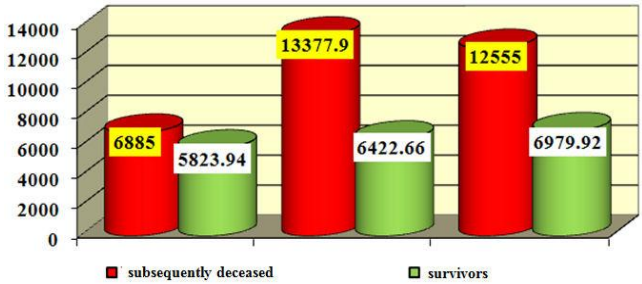

Fig. 2. Mean values of leucocytes (per mm^3)

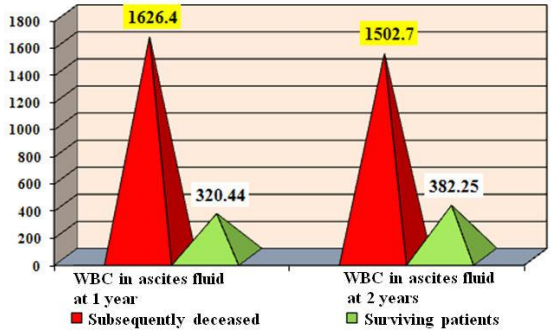

Fig. 3. Mean value of leucocytes in AF

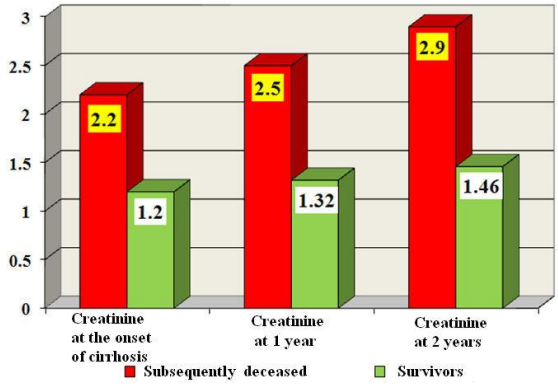

Fig. 4. Mean values of creatinine (mg/dL) in surviving patients compared to the dead ones

TABLE II

Statistical differences between the deceased and the survivors

Variables	Cases		Mean		Dev. std.		Minim		Maxim		p
	D	S	D	S	D	S	D	S	D	S	
Albumine	14	139	28.07	**32.05**	2.702	5.251	22	23	32	55	**0.0059**
Bilirubin	14	139	2.52	2.84	1.229	3.688	1.14	0.73	4.79	22	0.75
Creatinin	14	139	**2.94**	1.46	1.294	0.668	1.2	0.58	4.5	4	**<0,00001**
Natrium	14	139	127.79	130.84	2.694	10.360	120	65	131	154	0.28

The albumin levels are on average significantly higher in survivors, and creatinine is significantly higher in dead patients. So, maybe there is a significant relationship between death and these two variables. (tab. II, III, IV, fig. 5, 6)

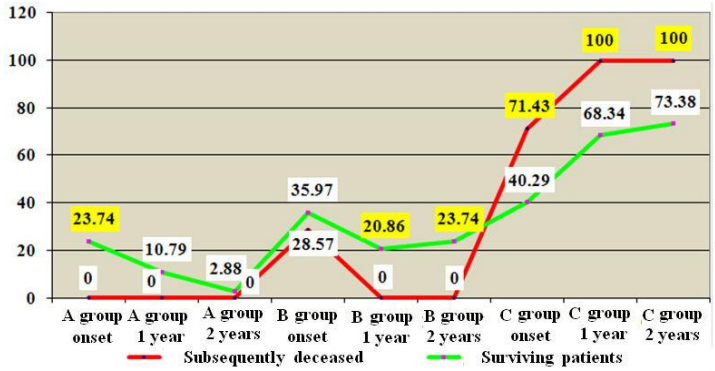

Fig. 5. Child classification in later deceased patients vs. Survivors

TABLE III

Frequency of hepato-renal syndrome in patients who subsequently died compared to survivors

2 years	3	**21,43**	11	*78,57*↓	6	*4,32*↓	133	**95,68**	χ2=3,99 **p=0,045**

DISCUSSION

Identification of patients with increased risk of death is extremely important in order to improve prognosis.

Terg and collaborators reported an increased mortality in patients with bilirubin over 4 mg / dL and serum creatinine over 1 mg / dl compared with those with low risk factors (23% vs. 6.5%) (10). Recent study by Luke et al. (11) showed that renal dysfunction, defined by a creatinine level higher than 1.5 mg / dl was the most important predictor of mortality in patients with SBP.

Almost one third of patients diagnosed with liver cirrhosis complicated with SBP develops hepato-renal syndrome, with a high mortality rate. Terg's recent study (10) showed that renal dysfunction, defined by a creatinine level higher than 1.5 mg / dl was the most important predictor of mortality in patients with SBP. They also demonstrate that hyponatremia is an independent risk factor of predicting mortality in cirrhotic patients with SBP (10, 12). MELD score predicts survival in cirrhotic patients at three months and in those enrolled in liver transplantation.

In those patients who subsequently died, the mean values of leukocytes in the blood, at both study onset and at examination 1 and 2 years, were significantly higher. Mean value of leukocytes and PMN in ascites fluid was significantly higher (about 4-5 times) in patients who subsequently died compared with the survivors.

Mean creatinine was significantly higher in patients who subsequently died, both at study onset and at examination 1 year and 2 years, assessing that renal dysfunction is a predictor of mortality in patients with decompensated cirrhosis.

Frequency of cases with hepato-renal syndrome at both examinations 1 year later and 2 years later was significantly higher in patients who later died.

Cases of infectious complications (other than SBP) were significantly more numerous (about 10 times) in patients who subsequently died (21.43% vs. 2.88%, p = 0.01). SBP frequency was significantly higher (3 to 7 times) in patients who later died, in all three stages of examination.

The frequency of variceal bleeding was significantly higher in patients who subsequently died, as also shown in the current literature (13).

Identification of new prognostic factors in patients with liver cirrhosis is important because recent research shows significant changes in the epidemiological profile, the number of multidrug-resistant bacteria is very high. Empirical therapy has been proved to be ineffective in these cases, antibiotics should be used according to the antibiogram results.

CONCLUSIONS

In our study the main conclusins are:

SBP mortality decreased substantially from 90% in 1970 to 10-30% today, but SBP still remains a complication with poor prognosis; Identification of patients with increased risk of death is extremely important to improve prognosis; Peripheral leukocytosis, and low hemoglobin in the ascites fluid, can be considered predictive of mortality in patients with SBP; Child-Pugh score, increased levels of bilirubin, creatinine, and hyponatremia are independent risk factors of mortality in patients with SBP; Bacteremia and the lack of therapeutic response are independent risk factors of mortality associated with SBP; Recent history of variceal gastrointestinal hemorrhage, severity of infection and the degree of hepatic and renal failure influence short-term prognosis of patients with SBP.

VALIDATION AND EVALUATION OF MEMORIAL SYMPTOM ASSESSMENT SCALE SHORT-FORM (MSAS-SF) IN A ROMANIAN COHORT OF HEMODIALYSIS PATIENTS (Abstract): **The aim** of this study was to validate the MSAS-SF in a Romanian hemodialysis (HD) population and to assess the prevalence and severity of physical and psychological symptoms of patients. **Materials and methods:** 102 stable patients (41 males, 61 females, mean age 52.51 ± 12.02 years), who were treated with hemodialysis (HD) three times weekly completed questionnaires on prevalence and severity of symptoms. To determine symptoms prevalence and severity for HD patients MSAS-SF was used. Cronbach`s alpha reliability test was performed to assess internal consistency of the MSAS-SF. **Results:** The Cronbach's alpha reliability score for the total number of items of the MSAS-SF was 0.838, while for the subscales of MSAS-SF the reliability scores ranged from acceptable to very good. The top three symptoms experienced by hemodialysis patients were lack of energy, followed by pain, and worrying. The most frequently reported physical symptoms included lack of energy (69.6%), pain (68.6%), and numbness /tingling in hands/feet (64.7%), difficulty sleeping (63.7%), dry mouth (61.8%), dizziness (58.8%), and problems with sexual interest or activity (52%). The most frequent psychological symptoms included worrying (65.7%), feeling sad (59.8%), feeling nervous (50%), and feeling irritable (40.2%). **Conclusions:** These results support the validity of the MSAS-SF in the assessment of Romanian patients undergoing hemodialysis. Hemodialysis patients have important psychological and physical symptoms burden. **Keywords:** END STAGE RENAL DISEASE, SYMPTOM BURDEN, HEMODIALYSIS, MSAS-SF.

The number of patients diagnosed with chronic kidney disease (CKD) is increasing, with recent studies suggesting that >10% of the population may have CKD (1). The total life expectancy of an individual with ESRD is only one-fourth to one-fifth that of the general population (2).

Physical and emotional symptoms are major concerns of chronic illnesses and represent a central role in patients` experience with life-threatening diseases. High symptom burden is associated with reduced health related quality of life (HRQoL) (3).

ESRD patients have a high burden of

disease (particularly cardiovascular co-morbidities) affecting their quality of life (QoL) and dramatically shortening life expectancy (4).

Stressors for individuals on hemodialysis can be treatment-related such as dietary and fluid restrictions and taking different medications, or psychosocial such as alterations in sexual function, changes in self-confidence, and panic of death (5). The symptoms that usually occur in treatment of dialysis are loss of appetite that may lead to a quick occurrence of metabolic disorders, mood reduction that also may result in willingness to give up treatment (6). Depressive symptoms and depression are the most frequent psychological problems reported among ESRD patients being treated by hemodialysis (*7*). Depression is significantly associated with mortality in dialysis patients (8).

Our objective was to validate, for the first time, the Memorial Symptom Assessment Scale (MSAS-SF) in a Romanian HD population and to assess the prevalence and severity of physical and psychological symptoms of HD patients using the MSAS-SF.

MATERIAL AND METHODS

We conducted an observational cross-sectional study, that comprised hemodynamic stable patients on hemodialysis treatment for at least six months from the Dialysis Center "Dr. C.I. Parhon" University Hospital, Iasi, Romania. The exclusion criteria were age under 18 years, psychiatric conditions, or any other medical condition that could severely interfere with completion of the scales. All included subjects gave informed consent before participating in the study. The study was approved by the Hospital's Ethical Committee and was performed in agreement with Helsinki's declaration of human rights.

Demographic characteristics, biochemical and dialysis parameters were obtained from the patients' medical records. All patients received HD a four hours/session, three times/week.. Kt/v represents a way of measuring dialysis adequacy. The current Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines on hemodialysis adequacy recommend that the minimally adequate dose for conventional, thrice-weekly treatment be a target dose of 1.4 (9). Interdialytic weight gain (IDWG) was calculated as the mean of IDWG of the last three dialysis sessions. Systolic and diastolic blood pressure values (SBP, DBP) were averaged, as well, from values before, during and after the finalization of the last three dialysis sessions.

The Memorial Symptom Assessment Scale - Short Form (MSAS-SF) (10) is a patient-rated instrument in which patient's rate symptom distress associated with 27 physical symptoms and the frequency of 4 psychological symptoms during the 7 past days. MSAS-SF subscales include: the global distress index (GDI) (4 psychological symptoms: feeling sad, worrying, feeling irritable, and feeling nervous, and 6 physical symptoms: lack of energy, pain, lack of appetite, feeling drowsy, constipation, dry mouth); the physical symptom distress score (PHYS) comprises 12 prevalent physical symptoms (lack of energy, pain, lack of appetite, feeling drowsy, constipation, dry mouth, nausea, vomiting, change in taste, weight loss, feeling bloated, and dizziness; the psychological symptom distress score (PSYCH) includes 6 prevalent psychological symptoms (worrying, feeling sad, feeling nervous, difficulty sleeping, feeling irritable, and difficulty

concentrating).

The data were analyzed using SPSS version 17.0 for Windows. Frequencies and descriptives statistics of the demographic and symptoms data of the study population were calculated. Cronbach alpha test was performed to assess internal consistency of the MSAS-SF. Independent Samples t test was used to compare means in male/female patients in MSAS-SF dimensions.

RESULTS

102 patients (41 males and 61 females) were enrolled in our study. The mean age was 52.51±12.02 years; patients` mean hemoglobin level 10.99±1.06 and mean kt/v 1.47±0.27. Patients had received renal replacement treatment (HD) for a mean duration of 10.79 ± 5.7 years (tab. I). The translated version into Romanian of the MSAS-SF proved to be comprehensible and easy to complete during the testing. All the participants considered that the items included in the test were relevant to patients with dialysis. Cronbach alpha reliability coefficients ranged from acceptable to very good, for all subscales of MSAS-SF. The Cronbach`s alpha coefficient for the total number of symptoms (MSAS-SF TNS) was 0.838. For GDI dimension (Global Distress Index) Cronbach`s alpha coefficient was 0.739, for PHYS dimension (Physical Symptom Subscale) was 0.648 and for PSYCH dimension (Psychological Symptom Subscale) the Cronbach`s alpha coefficient was 0.749.

The top three frequent symptoms experienced by hemodialysis patients were lack of energy, followed by pain, and worrying (tab. II).

The most frequently reported physical symptoms included lack of energy (69.6%), pain (68.6%), and numbness/tingling in hands/feet (64.7%), difficulty sleeping (63.7%), dry mouth (61.8%), dizziness (58.8%), and problems with sexual interest or activity (52%). The most frequent psychological symptoms that included worrying (65.7%), feeling sad (59.8%), feeling nervous (50%), feeling irritable (40.2%). The symptoms reported as most severe were difficulty sleeping (25.5%), numbness/tingling in hands/feet (11.8%), constipation (11.8%), itching (10.8%). HD patients seemed to ranked *difficulty sleeping* as the number one symptom that causes very much of distress. Also, we analysed the means scores of MSAS-SF dimensions in relation to gender of our included patients. There was no significant differences in symptoms frequencies between males and females for the all three MSAS-SF dimensions: GDI, PHYS and PSYCH ($p>0.050$) (tab. III).

Diarrhea	28	9 (8.8)	93 (91.2)
Mouth sores	29	7 (6.9)	95 (93.1)

TABLE III

Mean Scores of MSAS-SF Dimensions in Relation to Gender of Patients (N=102)

MSAS-SF Dimensions	Gender		p
	Male	Female	
Global Distress Index	11.30±7.04	10.74±6.64	0.688
Physical Dimension	10.56±6.63	10.23±6.24	0.801
Psychological Dimension	7.49±5.71	6.58±4.71	0.386

DISCUSSION

All three MSAS-SF subscales, namely GDI, PHYS and PSYCH had alpha Cronbach coefficients higher than 0.60, showing good reliability.

Symptom management became the focus of care for patients with advanced kidney disease including patients receiving renal replacement therapy. Lack of energy, pain and worrying were the most important physical symptoms, respectively psychological in our dialysis patients. In long-term dialysis patients, fatigue represents one of the common and troublesome problems that may influence the quality of life. Duration of dialysis is a factor that positively correlates with fatigue. Post-dialysis fatigue has been attributed to essential components of dialysis, i.e. ultrafiltration and diffusion, and the consequent rapid hydraulic and molecular flux (11).

Pain is common in patients who are in long-term hemodialysis (12). Headache is very common, usually restricted to the HD session. Typically, headache occurs in the last hour of the session (13). The incidence of headache was higher when patients had their treatment times increased from 4 to 5 h (14). Pain of muscoloskeletal origin was also found the most frequent form of chronic pain reported by patients who were on maintenance hemodialysis. Abdominal pain was the most gastrointestinal symptom, reported by 72% of HD patients (12).

Hemodialysis patients are subjected to multiple psychosocial and physiological stressors and may be threatened with many potential losses and lifestyle changes. In a recent research, limited vacantation, fatigue, uncertainty about future were the real causes for worry in HD patients (15).

It seems that the most distressful symptom reported by our hemodialysis patients was difficulty sleeping. From 65 patients who reported difficulty sleeping, a number of 26 mentioned this symptom as causing very much of distress. Sleep disorders are quite common in the hemodialysis patients, especially those who are anemic and hypoalbuminemic (16).

Our findings are consistent with those of other studies investigating the symptoms of chronic renal disease managed with dialysis. Weisbord et *al.* (17) found that HD patients reported a wide range of symptoms, including lack of energy (74%), feeling drowsy (63%), numbness/tingling in hands/feet (63%), dry mouth (58%), pain (53%), itching (53%).

In a study of assessing symptom prevalence in cancer patients, Tranner et al (18) found that lack of energy (83%), dry mouth (82%), pain (78%) were the most frequent physical symptoms. If findings from this study are compared with our study, then lack of energy and pain were equally common in both population, but dry mouth was much more prevalent for cancer population than for HD patients.

CONCLUSIONS

In our study the total number of symptoms experienced by our study patients was high and the most prevalent symptoms proving not to be the most distressing. Our results demonstrated that physical and emotional symptoms are prevalent and can be severe in patients who receive maintenance hemodialysis. MSAS-SF is a usefull tool in the assessment of physical and psychologial symptoms in Romanian patients undergoing hemodialysis.

CONGENITAL HEART MALFORMATIONS IN NEWBORN BABIES WITH LOW BIRTH WEIGHT (Abstract): congenital heart malformations represent a public health problem, holding a significant percentage of the total of heart diseases. Beside the elevated frequency of the malformations, we also notice their occurrence in newborn babies with low birth weight, increasing, thus, the risk of complications and late therapeutic approach. **The goal** of the study was to highlight the general and particular aspects of cardiovascular malformations epidemiology in newborn babies with low weight at birth, the correlation of the malformations with implied genetic and environmental factors, assessing the complications and their procedures on the therapeutic management. **Material and methods**: Our study was performed on a group of 271 patients, hospitalized in the Department of Pediatric Cardiology of "Sf. Maria" Emergency Clinical Hospital for Children of Iasi, during January 2011 – December 2013. The patients were assessed based on anamnesis, clinical, biological and imagistic exam. **Results**: The study lot was divided according to the type of the structural defect: 95% of the patients were diagnosed with non-cyanogenic congenital heart malformations and 5% with cyanogenic congenital heart malformations. Regarding the patient's origin background, we notice an elevated frequency of the rural environment (71%). The incidence of the malformations was high in premature low birth weight (48%), followed by premature very low birth weight (22%). In evolution, congenital heart malformations often get more complicated heart failure, arterial hypertension and respiratory infections being most often met. Mortality was maximum in the first year of life, a third of the cases being associated with chromosomal malformations. **Conclusions**: Congenital heart malformations in newborn patients with low weight at birth represented an elevated percentage of 44.13% of the total of the cases hospitalized for cardiovascular diseases from the Department of Pediatric Cardiology of Iasi. Many cases were associated with other congenital malformations or different complications, being necessary an interdisciplinary collaboration to adequately monitor the anatom5ical and functional parameters and to ensure a somatic and mental development as normal as possible. **Keywords**: CONGENITAL HEART MALFORMATIONS, LOW WEIGHT AT BIRTH, COMPLICATIONS

Congenital heart malformations are the result of an abnormal embryogenesis, characterized by structure or function anomalies of the cardiovascular system (1). Of a big importance is the early diagnosis, before the settlement of the irreversible complications that create a vicious circle on infantile mortality and morbidity. Each

year in Romania over 20,000 prematurely born babies and new-born babies with low weight at birth are registered. Prematurity and its complications are accountable for more than a half of the neonatal deaths, representing one of the main causes of neonatal mortality in our country (3).

MATERIAL AND METHODS

The study was retrospectively performed on a group of 271 newborns with low weight at birth within the Department of Pediatric Cardiology of "Sf. Maria" Emergency Clinical Hospital for Children of Iasi, during January 2011 - December 2013. All patients were anamnestically, clinically, biologically and imagistically examined, being divided in 2 sub-groups: non-cyanogenic congenital heart malformations and cyanogenic congenital heart malformations.

RESULTS

In this study, the cases with congenital heart malformations in newborns with low weight at birth represented 44.13% of the total of cases hospitalized for cardiovascular diseases in the Department of Pediatric Cardiology of "Sf. Maria" Emergency Clinical Hospital for Children of Iasi, in the chosen period. From the background environment point of view, 192 (71%) patients came from rural environment and 79 (29%) patients from urban environment. Maternal anamnesis showed that 50% of these are young mothers (16-30 years of age) and only a percentage of 28% presents extreme ages (36-49 years of age). The incidence of malformations proportionally varied with age, being higher in the premature low birth weight (48%), very low birth weight (22%), extremely low birth weight (6%).

The analysis of maternal pathology with possible teratogenic implications demonstrated that chronic diseases were present in 21 (7.58%) in the mothers of the children diagnosed with congenital heart malformations: DZ (6 cases), hypothyroidism, (6 cases), epilepsy (2 cases), HTA pregnancy pre-existence (8 cases), TBC (1 case). Anti-epileptic and tuberculostatic chronic medication during pregnancy was present in 1% of the cases, alcohol chronic consumption – 0.8% and viral infections (rubella, varicella, toxoplamosis, TORCH infections) - 2%.

The study group was divided according to the type of structural defect (fig. 1): 95% non-cyanogenic congenital heart malformations and 5% cyanogenic congenital heart malformations.

In the non-cyanogenic congenital heart malformations subgroup, the highest frequency was met in atrial septal defect cases (with a percentage of 43.10), the majority being of OS type. As frequency, patent *ductus arteriosus* (23.28%) follows, than ventricular septal defect (13.36% - with localization on membranous septum level in most of the cases). The anomalies of the right ventricle exit tract (pulmonary valve stenosis) were presented in 7.54% of the cases and the anomalies of the left ventricle exit tract in 7.76% of the cases, of which 4.31 % presents aortic stenosis (of bicuspid valve type) and 3.45% presents coarctation of aorta (fig.2).

Upon sex repartition, we noticed a slight increase in favor of the males, (59% - the most frequent being diagnosed with ventricular septal defects, patent *ductus arteriosus*, pulmonary valve stenosis, coarctation of the aorta and atrio-ventricular canal defects; the females were noted in 41% of the cases being diagnosed in most of the cases with aortic stenosis (fig.3).

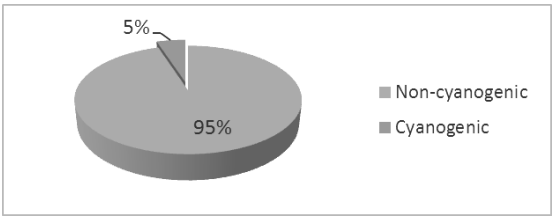

Fig. 1. Case distribution according to the type of the structural defect

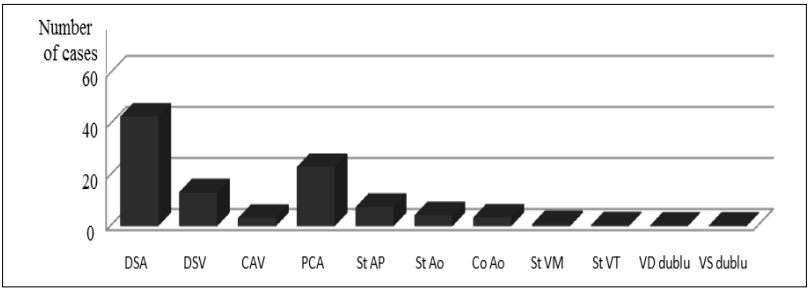

Fig. 2. Case distribution according to the different types of non-cyanogenic congenital heart malformations

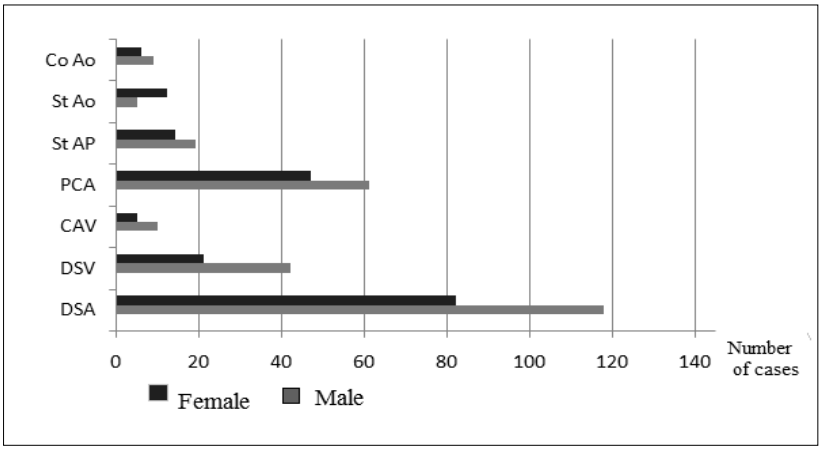

Fig. 3. Case repartition with non-cyanogenic congenital heart malformations according to the sex of the patients

Subsequent to the analysis of the anamnestic data regarding babies' gestational age and weight at birth, we notice that half of them had grade I prematurity, followed in equal proportions by cases with grade II prematurity and dismaturity.

The analysis of the electrocardiograms demonstrated that the majority of the patients were in sinus rhythm -97.37% and only 2.63% had irregular rhythm (atrial fibrillation). At the analysis of QRS complex morphology we noticed axis changes (16% - axis on the right 5% - axis on the left), atrial and ventricular hypertrophies and interventricular blocks (fig.4).

In evolution, non-cyanogenic CHM often complicated with IC, followed by pulmonary hypertension and respiratory condi-

tions (fig.5).

A number of 76 (17%) patients of the study subgroup were diagnosed with other congenital malformations. The analysis of associated genetic syndromes showed a predominance of chromosomal syndromes - 30 (6%) cases compared to monogenic ones -4 (0.89%) cases.

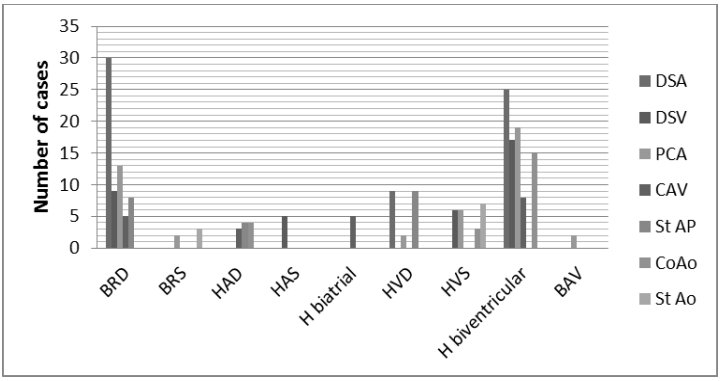

Fig. 4. Case repartition according to the electrocardiographic modifications

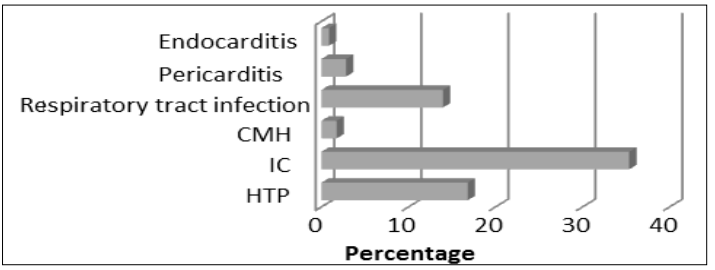

Fig. 5. Graphical repartition of the complications in patients diagnosed with non-cyanogenic congenital heart malformations

TABLE I

Genetic syndromes detected in children win non-cyanogenic congenital heart malformations

Chromosomal syndrome	Associated non-cyanogenic CHM	Number of total cases
Down	DSA OS	20
DiGeorge	DSA OS	4
Edwards	DSV	2
Turner	St AO	1
Cri du chat	PCA	1
Williams	St AP	1
Waardenburg	Co AO	1
Monogenic syndromes		
Marfan	DSA OS	1
Ehler Danlos	DSA OS	1
ADPKD	CAV	1
Dandy Walker	DSA OS	1

In the study subgroup of the cases with cyanogenic congenital heart disease, we noticed an increased frequency of cases with tetralogy Fallot (45%), followed by big vessel transposition (24%), Fallot pentalogy (19%). 0.2% of the total congenital heart disease represented the percentage in common for the cases that were diagnosed with common arterial trunk and sole ventricle (1 case each) (fig.6).

Repartition on sexes of cyanogenic congenital heart disease showed a slight difference in favor of the females (57%); males (43%) are especially met in cases diagnosed with transposition of the great arteries and sole ventricle (fig.7).

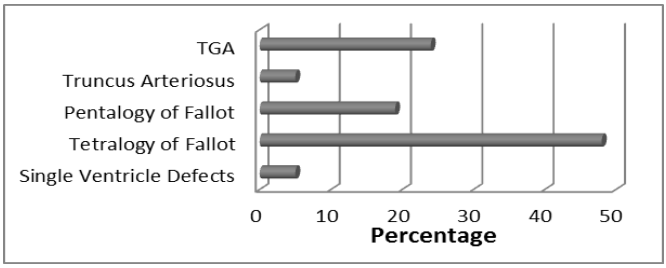

Fig. 6. Cyanogenic congenital heart disease case distribution

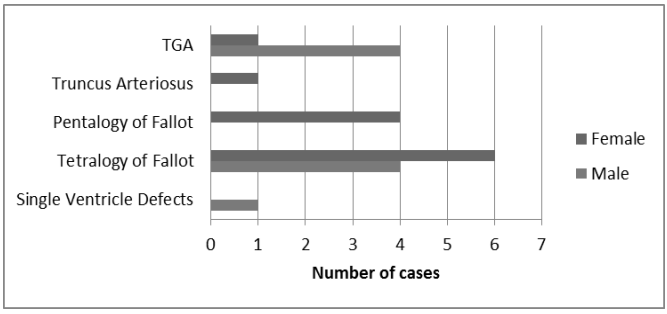

Fig. 7. Repartition to the sex of cases with cyanogenic congenital heart malformations

The X-ray exam brought a major contribution in Fallot tetralogy diagnosis (cord en sabôt-73% accompanied by pulmonary hyper-transparent - 55%) and transposition of the great arteries (narrowed superior mediastine 67%, ovoid heart 83% and pulmonary stasis 50%). In cases with sole ventricle and common arterial trunk, only an enlarged diameter of the heart and stasis aspect were described, requiring, thus, additional investigations.

At the analysis of the electrocardiograms, in 67% of the cases, we notice the deviation of the axis to the right, and in only 16% the intermediate axis. Right ventricular hypertrophy is presented in 7 cases of Fallot tetralogy of the 10 (64%) diagnosed, in 4 cases of transposition of the great arteries of the 6 (30.77%) non-diagnosed (30.77%) and in 1 case of Fallot Pentalogy of the 4 (25%) diagnosed. Biventricular hypertrophy was met in the case of the sole ventricle and common arterial trunk.

Three cases of syndromes were associated with other genetic syndromes: 2 cases with Di George syndrome and 1 case with fetal alcohol syndrome. Between 2011-2013, 18 children of non-cyanogenic CHM

group were operated (the most frequent defects being: DSV - 6 cases, PCA - 4 cases, and some 2 cases of CAV, Co AO, DSA, St AO), and 4 children were operated form the cyanogenic CHM group (3 cases with Fallot tetralogy and a case of TVM). An increased frequency of the surgery procedure was noticed in 2012 (fig.8).

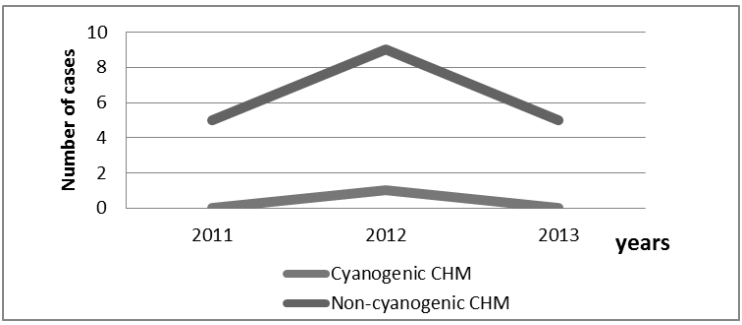

Fig. 8. Distribution on years of the corrective surgery procedure

The results of the anatomical and pathological exam were analyzed in 24 cases of the study group who died in the Department of Pediatric Cardiology of "Sf. Maria" Clinical Hospital for Children of Iasi during 2011-2013 and were confirmed by necropsy with congenital heart defect. The mortality of the cases diagnosed with congenital cardiovascular malformations was the maximum in the first year of life, when 96% of total number of deaths of the children with congenital heart defect was recorded. In the first week of life, 8% of the deaths of the children with congenital heart defect took place, and in the first month, half of deaths recorded in the first year (42%) (tab. II).

Regarding the sex of the deceased children with CHM, we notice a slight predominance of the males (13 cases - 54%). Congenital heart malformations that are the most implicated in tanatogenesis were represented by transposition of great arteries (40%), Fallot Tetralogy (25%) and atrioventricular canal defect (20%). One should note that, of the 24 deaths, a third was associated to chromosomal syndromes: Down syndrome (6 cases) and Edwards's syndrome (2 cases).

TABLE II

Death distribution in children with CHM according to the age the death took place

	Weeks	Months			Year
	0-1	1	1-3	3-12	>1
Number of cases	2	10	7	4	1
Percentage	8	42	29	17	4

DISCUSSION

Romania has got a prematurity indicator higher than many EU countries, the percentage of the babies born before 28 weeks and under 1,000 grams is approximately 1 – 1.5% of the total of living new-born. The figures vary depending on the geographical areas (Moldova and Muntenia having a higher prematurity rate). Besides the prematurity problem, the frequent occurrence of congenital heart malformations appears in this group of patients (3).

The pathology was dominant in the cardiovascular conditions diagnosed at a pediatric age in the Department of Pediatric Cardiology of „Sf. Maria" Clinical Hospital for Children of Iasi during 2011-2013, including only the group that had a low weight at birth, which resulted after anamnesis or hospital discharge note from neonatology department.

Upon analyzing the background environment, we notice a significant difference between urban and rural environment, control during pregnancy, early diagnosis of congenital heart disease and permanent monitoring being less often.

Different teratogens possible factors were tracked in 32 cases, representing 11.8% of the total CHM of the study group. Of the factors that intervened during pregnancy, we mention viral infectious factors (noticed in cases with DSA), chronic medication during some metabolic and neurological diseases, chronic alcohol consumption (met in cases with PCA and Fallot tetralogy). Thus, prevention by limiting exposure in collectivities, forbidding toxic substances consumption and a careful monitoring of the chronic diseases during pregnancy is very important (5, 11).

Most of the children included in the study, at birth were grade I (43%) premature, followed by dismature (25%) and a clinical state with APGAR score of 6-8 (80% of the cases) which demonstrates that the baby's sufferance is obvious since birth.

The analysis of the distribution on sexes shows a slight increase of the male children (55.71%) compared to female ones (44.29%).

Regarding the frequency of the different types of CHM in new-born with a low weight at birth; we recorded an elevated percentage of the atrial septal defect (43.10%) and a smaller percentage for patent *ductus arteriosus* (23.28%), which has the highest frequency in literature (2).

Dominant symptomatology was intense or moderated cyanosis with onset immediately after birth and/or decompensation of cardiacs globals with tachycardia, tachypnea, breathing in circulation, pulmonary rales, hepatomegaly. The weight deficit is an alarm sign suspecting congenital heart malformations: within non-cyanogenic congenital heart malformations, this one occupies 60% of the cases while in cyanogenic cardiac heart diseases the frequency is much more elevated (86%) (9).

Diagnose sensibility of the echocardiographical investigation in the studied cardiovascular malformations was much higher than electrocardiography and X-ray, but the results of the echocardiographical exam were interpreted only in the clinical and anamnesical context and in correlation with the results of EKG exam and X-ray (7).

The most frequent complications were the recurrent respiratory infections, heart failure, pulmonary hypertension and endocarditis (complication of ventricular septal defect in 2 cases, of patent ductus arteriosus - 1 case, atrioventricular canal defect - 1 case) (10, 12, 13).

Chromosomal malformations associated to congenital heart malformations have a different distribution compared to those mentioned in literature: ostium secundum atrial septal defects is associated with malformations of conjunctive tissue: Marfan and Ehlers Danles, aortic stenosis associated with Turner syndrome, Fallot tetralogy is frequently associated with Di George syndrome, atrioventricular canal defect with ADPKD. Hence, the genetic consultation during pregnancy is always indicated and very important in quantifying the postnatal risks (4, 6).

The death occurred in a number of 24

(8.8%) children; 8 (2.6%) of them having genetic syndromes, 12 (4%) being linked to pulmonary association and respiratory infections. The mortality of the cases was at maximum in the first year of life and none was operated (8).

CONCLUSIONS

In our study new-born patients with low weight at birth, diagnosed with CHM, represents an elevated percentage 44.13% of the total of hospitalized cases for cardiovascular diseases in the Department of Pediatric Cardiology of "Sf. Maria" Clinical Hospital for Children of Iasi, with a slight predominance of the males and of Grade I premature patients.

Under structural aspect, the cardiovascular malformations, analyzed in the descending order of the frequency, were: atrial septal defects, patent ductus arteriosus, ventricular septal defects, pulmonary valve stenosis, aortic stenosis, coarctation of the aorta, atrioventricular canal defects, tetralogy Fallot, transposition of great arteries, truncus arteriosus, sole functional ventricle.

Etiopathogenesis is pretty limited, but we have noticed the frequent association of Down syndrome with ostium secundum atrial septal defects and Edwards syndrome with ventricular septal defects, fact that leads to the increase of mortality of these cases.
